The Going Public Decision and the Product Market

Abstract

At what point in a firm's life should it go public? How do a firm's *ex ante* product market characteristics relate to its going public decision? Further, what are the implications of a firm going public on its post-IPO operating and product market performance? In this paper, we answer the above questions by conducting the first large sample study of the going public decisions of U.S. firms in the literature. Our findings can be summarized as follows. First, a private firm's product market characteristics (market share, competition, capital intensity, cash flow riskiness) significantly affect its likelihood of going public. Second, private firms facing less information asymmetry and those with projects that are cheaper for outsiders to evaluate are more likely to go public (consistent with Chemmanur and Fulghieri (1999)). Third, IPOs of firms occur at the peak of their productivity cycle (consistent with Clementi (2002)): the dynamics of total factor productivity (TFP) and sales growth exhibit an inverted U-shaped pattern. Finally, sales, capital expenditures, and other performance variables exhibit a consistently increasing pattern over the years before and after the IPO. The last two findings are consistent with the widely documented-post-IPO operating underperformance of firms being due to the real investment effects of a firm going public, and inconsistent with underperformance being solely due to earnings management immediately prior to the IPO.

The Going Public Decision and the Product Market

1. Introduction

“Going public” is one of the most important events in the life of a firm. Since an IPO of equity is the first public offering of equity (and typically the first public offering of *any* security) undertaken by the firm, it not only satisfies the immediate capital requirements of the firm, but also paves the way for the firm to make subsequent public offerings of equity and other corporate securities. Thus, going public allows the firm access to the public capital markets for the first time in its life, and hence may have important implications for a firm’s product market performance as well. However, while the going public decision has generated considerable theoretical research in recent years (see, e.g., Chemmanur and Fulghieri (1999), Maksimovic and Pichler (2000), and Clementi (2002)), empirically it is one of the least studied issues in corporate finance. In particular, there has been no empirical research so far focusing on the relationship between the product market characteristics of a firm and its decision to go public.

The objective of this paper is to bridge the above gap in the literature by addressing two related questions. First, what is the relationship between the *ex ante* product market characteristics of a firm and its going public decision? Second, how does going public affect a firm’s subsequent product market performance? Clearly, the answers to the above two questions are complementary, since the motivations of a firm to go public should, in the long run, be consistent with the actual effects of its going public. In the first part of our empirical analysis, we study the relationship between the *ex ante* product market characteristics of a firm immediately before going public and its likelihood of going public. In the second part of our analysis, we will study the dynamics of a firm’s product market performance in the years leading up to its IPO, and in the years after it has gone public. We conduct this latter analysis using two different samples. We first conduct this analysis of the dynamics of firm performance only using firms that eventually went public,

comparing the performance of these firms in the years before and after the IPO to their performance in the IPO year. We then perform this analysis using both firms that went public during our study period and those that remained private throughout, thus allowing us to compare the changes in the performance of firms going public to these changes in the performance of firms remaining private.

A number of theoretical models have implications (reviewed in detail in section 2) not only for the relationship between a firm's *ex ante* product market characteristics and its going public decision, but also for the dynamics of these characteristics before and after a firm's IPO. Chemmanur and Fulghieri (1999) model the going public decision in an environment of asymmetric information. In their setting the decision to go public emerges from the trade-off between raising capital from a number of well-diversified investors in the public equity market (thus avoiding the risk-premium charged by private financiers like venture capitalists who provide a significant fraction of the capital required for any given firm), and the duplication of outsiders' evaluation (information production) costs that arises from raising capital from a larger number of investors. This theory implies that larger and more capital intensive firms, with riskier cash flows, and those operating in industries characterized by lower evaluation (information production) costs (and a smaller extent of asymmetric information) are more likely to go public. Bhattacharya and Ritter (1983) and Maksimovic and Pichler (2000) argue that the decision to go public emerges from the trade-off between the costs of increased product market competition arising from the firm having to release confidential information (helpful to competitors) at the time of IPO, and the benefits arising from raising capital at a cheaper rate in the public equity markets. These theories imply that firms with greater existing market share, and those operating in industries characterized by a lower degree of competition, are more likely to go public. Finally, Clementi (2002) argues that firms go public as a result of a positive and persistent productivity shock: while a borrowing constraint kept the firm operating at a suboptimal scale before the shock, the deviation between actual and efficient scale becomes wider after the shock, making it optimal for the firm to go public

(and expand scale) despite the fixed costs of going public. This theory implies that firms characterized by greater productivity, output growth, and capital expenditures are more likely to go public.¹ We will test these and other implications here.

As noted before, the empirical research on the going public decision is scant, since privately held firms are typically not required to report their financial results and consequently the data required for this research is not readily available. There are only three pieces of direct research on this topic to date. The seminal paper on the going public decision is Pagano, Panetta, and Zingales (1998), who investigate a sample of Italian firms using a data set provided by a consortium of Italian banks. In more recent research, Fischer (2000) investigates a sample of privately held German firms, some of which went public on the *Neuer Markt*. While providing considerable insight into the going public decision, it is difficult to argue that the results of the above two papers generalize to the U.S. For example, only 69 of the more than 2000 firms eligible to go public in the PPZ sample went public in over 10 years; of these, more than 40 percent were equity carve-outs. Further, the typical newly listed company in Italy is several times larger and older than its counterpart in the U.S. Finally, the tax and regulatory environment in the U.S., and the stage of development of the U.S. capital markets are dramatically different from those in Italy. Several concerns apply to generalizing German evidence to the U.S. as well.² The only direct empirical evidence regarding the going public decisions of U.S. firms is provided by Helwege and Packer (2003), who make use of a sample of 178 non-financial firms mainly consisting of firms which had to file financial reports with the S.E.C. since they issued publicly traded bonds *prior* to

¹ For other theoretical analyses having implications for the going public decision, see Subrahmanyam and Titman (1999), who study how the decision to go public is affected by outsiders obtaining serendipitous information, and Pagano and Roell (1998), who analyze how agency considerations affect the going public decisions.

² Apart from the dramatic differences in the tax and regulatory environment in the U.S. and in Germany, there are also significant differences in the stage of development of the capital markets in Germany and in the U.S. Thus, while the number of IPOs on the Neuer Markt rose sharply during the late 1990s, it had fewer than 100 IPOs per year even during the most active period in Germany, the equivalent of a weak year in the U.S.

their IPO.³ While providing some insight into the going public decisions of U.S. firms, it is doubtful whether their results also generalize to the bulk of private firms in the U.S., given that private firms which issue public bonds before their IPO tend to be large and highly leveraged, (in contrast to the average firm going public in the U.S. which tends to be small and with much less leverage), and that only about 35 firms (one fifth) of their sample attempted to go public during their study period. In contrast to the above existing literature, we are able to analyze the going public decisions of U.S. firms using a large and representative sample of U.S. manufacturing firms: our study uses the Longitudinal Research Database (LRD) of the U.S. Bureau of Census, which covers the entire universe of private and public manufacturing firms in the U.S.

A secondary objective of this paper is to shed new light on the operating underperformance of firms subsequent to IPOs. While a number of papers (see, e.g., Jain and Kini (1994) and Mikkelsen, Partch, and Shah (1997)) have documented that firms that go public underperform their peers in terms of operating performance, the reason for this underperformance is controversial. Several alternative explanations have been proposed for this underperformance, including the idea that operating underperformance is due to earnings management or “creative accounting” by firms going public (we review some of these hypotheses about the dynamics of firm performance in section 2.2). Our analysis is able to provide new insights on the relative merits of these hypotheses for two reasons. First, we are able to examine the operating performance of firms going public for a number of (five) years *before* the IPO, in contrast to existing studies, which focus only on operating performance in the two years before the IPO and the years subsequent to the IPO (possibly due to the data limitations discussed before). Second, in contrast to earlier studies (which focus on accounting numbers), we focus on performance measures such as the total factor productivity (TFP) which are derived from a variety of different measures of firm performance, and are thus less subject to manipulation compared to accounting numbers.

³ A few of the firms in the Helwege and Packer (2003) sample were not public bond issuers, but nevertheless had to file financial reports with the SEC because they had a very large number of shareholders despite their private status.

Our findings on the relationship between the *ex ante* product market characteristics of a firm and its likelihood of going public can be summarized as follows. First, we find that firms which are larger in size and have higher sales growth are more likely to go public. Second, firms with have greater productivity (TFP), greater market share, and those with projects which are cheaper for outsiders to evaluate are more likely to go public. Third, we find that firms operating in less competitive and more capital intensive industries, and those characterized by riskier cash flows are more likely to go public. Fourth, we find that firms in industries characterized by less information asymmetry between firm insiders and outsiders (as measured by the averages of various proxies of information asymmetry for firms already listed in that industry, like standard deviation of analyst forecasts, and analyst forecast error) and greater average liquidity of already listed equity are more likely to go public. While the first set of findings above are consistent with those documented by Pagano, Panetta, and Zingales (1998) for Italian firms, and Helwege and Packer (2003) for bond-issuing U.S. firms, we are the first in the literature to document the second, third, and fourth set of results above. The above findings are consistent with the implications of three of the theories of going public mentioned above, namely, the information production theory of Chemmanur and Fulghieri (1999); the confidential information release theory of Bhattacharya and Ritter (1983) and Maksimovic and Pichler (2000); and the productivity shock theory of Clementi (2002).

Our analysis of the dynamic pattern of firm performance before and after the IPO indicate that total factor productivity (TFP) increases steadily in the five years prior to the IPO, reaches a peak in the IPO year, and declines steadily in the years subsequent to the IPO (i.e., TFP exhibits an inverted-U shape). Sales growth exhibits a similar pattern, increasing in the years prior to the IPO, and declining in the years subsequent to the IPO. However, sales, capital expenditures, employment, total labor costs, materials costs, and sales and administrative expenses exhibit a consistently increasing pattern both in the years before and after the IPO. Our results indicating declines in productivity post-IPO, and the pattern of sales and capital expenditures of firms

subsequent to the IPO, are consistent with the prior empirical literature (e.g., Jain and Kini (1994) and Mikkelson, Partch, and Shah (1997)) which has documented operating underperformance subsequent to the IPO (albeit using accounting measures such as return on assets (ROA)). However, the dynamic pattern in various firm performance variables before and after the IPO (and especially the inverted-U shaped pattern of productivity changes) that we document around the IPO is inconsistent with the notion that the operating post-IPO underperformance of firms is generated solely by earnings management by firms immediately prior to the IPO. In particular, the consistent growth in firm productivity that we document for *five years* before the IPO is unlikely to be generated purely by the manipulation of accounting numbers, since the performance effects of such manipulation are likely to be confined to the years immediately prior to the IPO, and would not persist over so many years (especially given the fact that measures of economic performance such as TFP, being derived from a variety of different performance measures, are much harder to manipulate compared to accounting numbers). Instead, the above dynamic pattern of various variables (and especially the inverted-U shaped pattern of productivity changes) is broadly consistent with the performance implications of a firm increasing its scale of operations around the IPO (making use of the external financing raised), as characterized by the theoretical analysis of Clementi (2002), which we discuss in detail in section 2.2.

The rest of the paper is organized as follows. Section 2 reviews various theories of the going public decision, and develops hypotheses, both for our empirical analysis of the relationship between *ex ante* product market characteristics of a firm and the likelihood of it going public (section 2.1) and our analysis of the dynamic pattern of firm performance before and after the IPO (section 2.2). Section 3 describes our data and explains the construction of various variables used in the study. Section 4 presents our empirical tests and results on the relationship between the *ex ante* product market characteristics of a firm and its likelihood of going public. Section 5 presents our empirical tests and results on the dynamic pattern of firm performance before and after the IPO. Section 6 concludes.

2. Theory and Hypotheses

In section 2.1, we will review the theoretical literature relating the ex ante product market characteristics of a firm and the likelihood of its going public and develop hypotheses for the empirical tests we present in section 4. Similarly, in section 2.2, we will review the implications of various theories for the dynamics of firm characteristics around the IPO and develop hypotheses, which will serve as the basis for the empirical tests we present in section 5.

2.1 Relationship between Product Market Characteristics and the Going Public Decision

Chemmanur and Fulghieri (1999) model a firm's going public decision in an environment where insiders have private information about firm value, but where outsiders can produce information about firm value (i.e., "evaluate the firm") at a cost. If a firm raises capital by going public, it faces duplication in outsiders' information production costs (ultimately, outsiders' information production costs are born by the firm through a lower share price), since it needs to convince a number of investors that the firm's projects are worth investing in. In contrast, if it raises capital privately (e.g. from a venture capitalist), there is no such duplication in information production, but the provider of private financing will charge a risk premium over his cost of funds, since he is taking an undiversified position in the firm. When the firm is small, young, or otherwise faces severe information asymmetry, or is in a "complex" industry where the firm's project is hard to evaluate (so that outsiders' evaluation cost is high), the cost of duplication in outsiders' information production outweighs the premium demanded by private financiers, and the firm chooses not to go public. Conversely, if the firm is older, larger, or is otherwise easier to evaluate for outsiders (so that each investor's evaluation cost for the firm is low) the effect of the above duplication in information production is outweighed by the premium demanded by the private financiers, so that the firm chooses to go public. Further, since more of the private financier's

capital will be tied up in a single firm if the firm is in a more capital intensive industry (or in a riskier industry), such a firm is more likely to go public (*ceteris paribus*), since, for such a firm, the above discussed tradeoff between staying private and going public is likely to favor going public at a larger level of the outsiders' evaluation cost of the firm.⁴

In summary, the above theory leads to the following testable predictions:

H1: Smaller and younger firms are less likely to go public.

H2: Firms operating in industries characterized by less information asymmetry and more stock market liquidity are more likely to go public.

H3: Firms operating in industries where it is easier for public investors to evaluate the firm are more likely to go public.

H4: Firms operating in more capital intensive industries and in those characterized by greater riskiness of cash flows are more likely to go public.

Bhattacharya and Ritter (1983) and Maksimovic and Pichler (2001) develop models of the going public decisions of firms driven by product market competition between innovative private firms in an industry. In their setting, raising capital in the equity market by going public allows a firm which is an industry leader to raise external capital (at a cheaper rate than private financing), thus allowing it to implement its project at its optimal scale. However, going public has the disadvantage of releasing confidential information to competing firms, which can then compete more effectively with the firm going public.⁵ Their arguments imply that, if a firm has a larger market share in its industry, its benefit from expanding scale by going public is likely to be greater (for a given cost of going public) so that such firms are more likely to go public. Conversely, if the degree of concentration in the firm's industry is greater (so that the firm faces less competition), its costs of going public will be lower, making it more likely to go public. Further, firms operating in

⁴ Subrahmanyam and Titman (1999) models information externality in an IPO. Their model yields the similar predictions as Chemmanur and Fulghieri (1999).

⁵ Campbell (1979) was the first to point out the danger of a firm releasing confidential information to product market competitors at the time accessing the capital market. Similar arguments have also been made by Yosha (1995).

industries where the value of confidentiality is greater (e.g., firms in high tech industries) are less likely to go public.

In summary, the above theory leads to the following testable predictions:

H5: Firms with a greater market share in their product market are more likely to go public.

H6: Firms operating in more concentrated industries are more likely to go public.

H7: Firms operating in industries where the value of confidentiality is greater (e.g., high tech firms) are less likely to go public.

Clementi (2002) builds a dynamic stochastic model of firm behavior explicitly incorporating the going public (IPO) decision. In his model, the firm operates in an industry characterized by decreasing returns to scale. Further, going public is costly, and prior to going public, a borrowing constraint keeps the firm's scale of production at a suboptimal level. In such a setting, the decision to go public is triggered by a sudden and persistent increase in the firm's total factor productivity (resulting in a new set of positive NPV projects becoming viable to the firm). Such a productivity shock has the effect of widening the gap between the efficient and the actual capital level of the firm, so that the marginal benefit of expanding operations (i.e., undertaking the additional positive NPV projects available to the firm) by going public outweighs the marginal cost of going public. The above theory implies that firms that have greater levels of total factor productivity (TFP) are more likely to go public. Further, firms will have higher levels of output growth and higher levels of capital expenditures relative to their private counterparts immediately prior to going public (since such firms are in the process of expanding the scale of their operations as a result of their productivity shock).

The above theory therefore has the following testable predictions:

H8: Firms with higher total factor productivity (TFP) are more likely to go public.

H9: Firms with higher levels of output growth and higher levels of capital expenditures are more likely to go public.

2.2 The Dynamics of Firm Characteristics Before and After the IPO

Several theories have implications for the dynamics of firm characteristics around the IPO. In particular, the model of Clementi (2002) discussed above has implications for firm productivity, sales, and capital expenditures before and after the IPO. In its early stages, when the firm is a start-up, the borrowing constraint precludes the entrepreneur from reaching its efficient size. While an infusion of capital would allow the firm to bridge the gap at least partially between actual and efficient capital, going public too early in its life is not optimal, since it involves incurring the fixed costs of doing so. The optimal policy of the entrepreneur is therefore to wait for a large enough positive productivity shock, so that the benefits of going public exceed the costs of doing so: at this point, the firm goes public, increasing its scale of operations. Once this occurs, however, measures of performance and productivity will start declining due to decreasing returns to scale, so that according to Clementi (2002), one can expect an inverted U-shape in the pattern of firm productivity around the IPO (with the peak productivity occurring roughly in the year of the IPO).

Clementi (2002) also has implications for the dynamic pattern of sales (output), capital expenditures, and employment, as well as materials and other costs of the firm around the IPO. Since the firm experiences a (series of) positive productivity shock(s) prior to the IPO and increases its scale of operations, capital expenditures and output increase in the years prior to the IPO and in the year of the IPO. Further, assuming that it takes time to put physical capital in a condition to be productive, the above model would predict that the firm's scale of operations (capital expenditures, output) would continue to increase for a few years after the IPO. In summary, the above model would predict that sales and capital expenditures would increase monotonically before and after the IPO. Further, total employment, total wages, materials costs, and rental and administrative expenses would also show increases in the periods before and after the IPO corresponding to the increases in the firm's scale of operations. Finally, the above theory would predict that while output (sales) growth will either remain steady (or may even increase) in the years immediately before the IPO (as the firm increases its scale of operations toward its

optimal level), output growth will be much smaller subsequent to the IPO (since the firm would have come close to its optimal scale soon after the IPO).⁶

The predictions of the above theory for the dynamics of firm characteristics differs markedly from those of other theories. One such theory (see, e.g. Teoh, Welch and Wong (1998)) is the earnings management or “creative accounting” explanation. This theory argues that, immediately prior to the IPO, firms have the incentive to show superior earnings by increasing current accruals (for example, by advancing the recognition of revenues, or by delaying recognition of expenses), in an attempt to obtain a better share price in the IPO. This theory would predict that while reported operating performance would peak in the pre-IPO year, they would decrease smoothly post-IPO. Our empirical analysis of the dynamics of firm characteristics would allow us to test whether the documented post-IPO decline in operating performance is due to earnings management or not, for two reasons. First, performance measures such as TFP are clearly less subject to manipulation compared to accounting numbers, since they are derived from a variety of different measures of firm performance. Second, we study various measures of firm performance for a number of years (five) before the IPO as well as after the IPO. It is unlikely that, even if firms attempt to manipulate their reporting of performance numbers prior to their IPO, they will be able to show consistently superior performance for many years pre-IPO purely by manipulating these numbers.

A third possible reason that has been advanced in the literature for the decline in the operating performance of firms subsequent to their IPO is the reduction in stock ownership by the entrepreneur and other top managers in the firm (which, in turn, reduces their incentives to expend effort to maximize firm value, for the reasons first outlined by Jensen and Meckling (1977)). However, unlike the previous two theories, this “incentive” theory does not predict an increase in

⁶ This last prediction requires the additional assumption that, as the firm gets closer to its optimal scale of operations; its rate of adjustment toward this optimal scale gets smaller.

firm performance prior to the IPO, since managerial ownership does not increase (and often decreases) in the years prior to IPO.

While the above theories have predictions regarding the dynamics of various firm characteristics around its IPO, the arguments made by Bhattacharya and Ritter (1983) and Maksimovic and Pichler (2001) (discussed in the previous section) have interesting predictions for the dynamics of an IPO firm relative to its product market competitors around its IPO. In particular, it has implications for its market share. If the information gleaned by a firm's competitors at the time of its IPO actually allows them to compete more effectively against it (and this effect dominates the effect of the firm having easy access to the equity market after its IPO and thus being able to implement its project more effectively) then the firm's market share should decrease subsequent to its IPO. In contrast, if the effect of the firm's easy access to the equity market in fact dominates the negative effects of having to release sensitive information at the time of IPO, the firm's market share should increase in the years following its IPO.

3. Data and Sample Selection

The primary data that we use in this study is the Longitudinal Research Database (LRD), maintained by the Center of Economic Studies at the U.S. Bureau of Census.⁷ The LRD is a large micro database which provides plant level information for firms in the manufacturing sector (SIC codes 2,000 to 3,999). The LRD tracks approximately 50,000 manufacturing plants every year in the Annual Survey of Manufacturers (ASM), which covers all plants with more than 250 employees. In addition, it also includes smaller plants that are randomly selected every fifth year to complete a rotating five year panel. In the census years, the LRD covers the entire universe of manufacturing plants in the Census of Manufacturers (CM). Most of the data items reported in the

⁷ See McGuckin and Pascoe (1988) who provide a detailed description of the Longitudinal Research Database (LRD) and the method of data collection.

LRD (e.g., the number of employees, employee compensation, and total value of shipments) represent items that are also reported to the IRS, thus increasing the accuracy of the data.

The crucial advantage of using the LRD data relative to COMPUSTAT data in this study is that the LRD covers both public and private firms in the manufacturing industries. The comprehensive coverage of private firms and the IPO firms in their private stage enables us to examine the product market determinants of the going public decision.⁸ Moreover, the panel format of the LRD (1972-2000) provides data on both the private and the IPO firms consistently through time. This allows us to examine the dynamics of the IPO firms' performance both pre- and post-IPO, benchmarked against their private peers. Another advantage of using the LRD for this study is that it enables us to construct precise measures of firms' product market performance. In addition to product market measures from the LRD, we also use CRSP and I/B/E/S for constructing measures related to stock market liquidity and information asymmetry respectively.

Our sample of IPOs is drawn from Security Data Corporation's (SDC) Platinum New Issues Database. As in most empirical studies on IPOs, we removed from our sample all IPOs related to equity-carve outs, ADRs, ADSs, global deposit recs, global deposit shares, units, trust receipts, and trust units. We also require that the primary industry of the firm going public is within the manufacturing sector (SIC 2000 to 3999) and that the firm is present on the Compustat annual industrial database for the fiscal year of the IPO. Thus our sample of IPOs from SDC comprises 2578 firms during the years 1972 to 2000. We match this sample of IPO firms to the LRD using the LRD-COMPUSTAT bridge file. Out of the 2578 firms, we matched 1315 firms to the LRD.⁹ In addition, we also identified all public firms in the LRD using the bridge file. These are public firms that had an IPO prior to the start of our sample period, i.e. 1972. In our analysis of the going public

⁸ Unfortunately, due to the data limitations, we are not able to look at the ownership composition and capital structure of the firm before going public.

⁹ The discrepancy in the number of IPOs between the LRD and SDC is mostly due to the incorrect industry classification of the firm in the SDC. Often times a manufacturing firm in the SC was not defined as manufacturing by the Bureau of Census. The sample of IPO firms that matched to the LRD are within a span of five years around the IPO date.

decision we eliminate these public firms. Thus our final sample in the regression analysis contains all firms remaining private through out the years 1972 to 2000 and the firms which went public between 1972 to 2000. Since the LRD provides plant level information, we aggregated all the plant level measures to the firm level by the firm identifier provided in the LRD.¹⁰

Table 1 presents the industry distribution at the 2 digit SIC level of the firms that went public in our sample. For disclosure reasons, we are not able to report the actual numbers for all the industries. Hence, in some cases we report it as ND (not disclosed). However, we can see that the IPO sample is very much representative of U.S. IPOs in the manufacturing sector, with some concentration in electronics and precision instruments industries.

3.1 Measurement of Total Factor Productivity (TFP)

Total Factor Productivity (TFP) is calculated from the LRD for each individual plant at the annual four digit (SIC) industry level. The total factor productivity of the firm is then calculated as a weighted sum of plant Total Factor Productivities (TFP) at the annual four-digit industry level. We obtain measures of TFP at the plant level, by estimating a log-linear Cobb-Douglas production function for each industry and year. Industry is defined at the level of four-digit SIC codes.¹¹ Individual plants are indexed i ; industries j ; for each year t , in the sample:

$$\ln(Y_{ijt}) = \alpha_{jt} + \beta_{jt} \ln(K_{ijt}) + \gamma_{jt} \ln(L_{ijt}) + \delta_{jt} \ln(M_{ijt}) + \varepsilon_{ijt}, \quad (1)$$

We use the LRD data to construct as closely as possible the variables in the production function. Output (Y) is constructed as plant sales (total value of shipments in the LRD) plus changes in the value of inventories for finished goods and work-in-progress. Since we appropriately deflate plant sales by the annual industry specific price deflator, our measure is

¹⁰ For TFP we aggregated the plant level measures using a value weighted approach, where the weights on the plants are the ratio of its sales to the total sales of the firm. As a robustness check, we also used the ratio of plant employment to firm employment as weights. The results obtained are similar in both cases. For firm age, we use the age of the earliest plant belonging to that firm.

¹¹ As a robustness check, we re-estimate the production function using two and three digit SIC industry classifications. We also estimate TFP with value added production function specifications and separate white and blue collar labor inputs. In all cases we find similar results.

proportional to the actual quantity of output. Thus, the dispersion of TFP for firms in our sample almost entirely reflects dispersions in efficiency.

Labor input (L) is defined as production worker equivalent man hours. This is the product of production worker man-hours, and the ratio of total wages and salaries to production worker wages. We also re-estimate the TFP regression specifying labor input to include non-production workers. Results remain qualitatively the same. Values for the capital stock (K) are generated by the recursive perpetual inventory formula. We use the earliest available book value of capital as the initial value of net stock of plant capital (this is either the value in 1972, or the first year a plant appears in the LRD sample). These values are written forward annually with nominal capital expenditure (appropriately deflated at the industry level) and depreciated by the economic depreciation rate at the industry level obtained from the Bureau of Economic Analysis. Since values of all these variables are available separately for buildings and machinery, we perform this procedure separately for each category of assets. The resulting series are then added together to yield our capital stock measure. Finally, material input (M) is defined as expenses for the cost of materials and parts purchased, resales, contract work, and fuel and energy purchased, adjusted for the change in the value of material inventories. All the variables are deflated using annual price deflators for output, materials, and investment at the four-digit SIC level from the Bartelsman and Gray NBER Productivity Database.¹² Deflators for capital stock are available from the Bureau of Economic Analysis.¹³

This measure of TFP is more flexible than the cash-flow measure of performance, as it does not impose the restriction of constant returns to scale and constant elasticity of scale. Also, since coefficients on capital, labor, and material inputs can vary by industry and year, this specification allows for different factor intensities in different industries. These production function estimates are pooled across the entire universe of manufacturing plants. The TFP measure for each

¹² See Bartelsman and Gray (1996) for details.

¹³ For a detailed description of the construction of TFP measures from LRD variables see Lichtenberg (1992).

individual plant is the estimated residual of these regressions. Thus, it is the difference between the actual output produced by the plant compared to its “predicted output”. This “predicted output” is what the plant should have produced, given the amount of inputs it used and the industry production technology in place. Hence a plant that produces more than the predicted amount of output in any given year has a greater than average productivity for that year. Thus, TFP can be understood as the relative productivity rank of a plant within its industry in any given year. Since these regressions include a constant term, TFP only contains the idiosyncratic part of plant productivity.¹⁴ Plant level TFP measures are then aggregated to the firm level by a value weighted approach, where the weights on the plants is the ratio of its output (total value of shipments) to the total output of the firm. The firm level TFP is winsorized at the 1st and 99th percentile.

3.2 Measures of Firm specific, Industry specific, Information Asymmetry, and Control Variables

In this subsection we discuss the construction and measurement of the different firm specific product market variables as well as the proxies in our regression analysis. The LRD data contains detailed information at the plant level on the various production function parameters, such as total value of shipments, employment, labor costs, material costs, new capital investment for the purchase of buildings, machinery, equipments etc. Using these detailed information, we first construct the variables of interest at the plant level, and then aggregate the plant level information to firm level measures.

Capital stock is constructed via the perpetual inventory method, which has been discussed earlier in section 3.1. We measure age as the number of years since the firm first appeared in the

¹⁴ As a robustness check for our regression results we use an alternative measure of productivity; value added per worker, which is defined as total sales less materials cost of goods sold, divided by the number of workers. This measure has been used in McGuckin and Nguyen (1995) and Maksimovic and Phillips (2001). This measure does not have the desirable theoretical properties of TFP, but does have familiar statistical properties, since it is not computed from a regression.

LRD.¹⁵ Sales is defined as the total value of shipment in thousands of dollars. Capital expenditure is the dollar value the firm spends on the purchase and maintenance of plant, machinery, and equipment etc. Material cost is the expenses for the cost of materials and parts purchased, resales, contract work, and fuel and energy purchased. Rental and administrative expenditure is the rental payments or equivalent charges made during the year for the use of buildings, structures, and various office equipments. Total wage is the total payroll of the firms. Average wage is the total wage over total employment. All the dollar values in the LRD are in thousands of dollars and all the firm level measures are winsorized at the 1 percentile and 99 percentile.¹⁶

To test *H1*, and also to control for firm size in other specifications, we define firm size (*SIZE*) as the natural logarithm of capital stock of the firm.¹⁷ We define age as the natural logarithm of age (*AGE*) in our regression analysis. As postulated in *H1*, we expect a positive relationship between *SIZE*, *AGE* and the probability of going public.

To test the effect of firm productivity on its decision to go public (*H8*), we calculate the total factor productivity (*TFP*) measure for each firm within each industry¹⁸. This measure of TFP captures a firm's productivity level relatively to its industry peers. A firm that enjoys high productivity is one that is able to produce more output per unit of input. Empirically, we expect *TFP* to have a positive effect on firm's decision to go public.

Capital intensity (*CAPINT*) is defined as firm's capital stock over total employment. According to *H4*, *CAPINT* is expected to have a positive relationship with the probability of going public. In order to proxy for industry risk (*INDRSK*), we calculate the industry median of the five years coefficient of variation of firm sales at the 3 digit SIC level. According to *H4*, we expect *INDRSK* to have a positive relationship with the probability of going public.

¹⁵ Though this is not a perfect measure, given the sampling scheme and scope of LRD, this measure is highly correlated with the actual age of the firm. Particularly, the relative age across firms, which is more relevant to the probability of going public, is well represented by this measure.

¹⁶ All dollar values are in 1998 real terms.

¹⁷ For robustness, we also rerun our regressions using log(employment) and log(sales) as proxies of firm size. The results remain qualitatively unchanged.

¹⁸ For detailed explanation of the TFP calculation, see section 3.1.

We define capital expenditure ratio (*CAPR*) as the firm's capital expenditure over capital stock. This measure captures the relative investment intensity of firms. We define sales growth (*SGTH*) as the average growth in sales in the past three years.¹⁹ Based on *H9*, we expect positive relationships between *CAPR*, *SGTH* and the probability of going public.

Market share (*MSHR*) is defined as the firm's market share in terms of sales at the 3 digit SIC level. We use the market share of the firm to proxy for the firm's industry leader position. Based on *H5*, a higher market share is expected to have a positive effect on the probability of going public. We construct the industry herfindahl index (*HI*) based on the market share measure of each firm in the LRD. The herfindahl index is calculated by summing up the square of each firm's market share (in sales) at the 3 digit SIC level. A higher herfindahl index means that the industry is more concentrated. According to our hypothesis *H6*, firms in more concentrated industries are more likely to go public. Hence, we expect a positive relationship between the industry herfindahl index and the probability of going public. We define high tech (*HTEK*) companies by the 3 digit SIC code in 357, 366, 367, 372, 381, 382, 384.²⁰ According to *H7*, *HTEK* is expected to have a negative relationship with the probability of going public.

The share turnover (*TOV*) measure and number of public firms listed in CRSP (*LIST*) are industry level measures constructed from CRSP. These measures are constructed as proxies to test *H2* and *H3* respectively. We use the mean of the share turnover across the public firms in the same 3 digit SIC industry to proxy for the expected liquidity in that industry and expect it to have a positive effect on the probability of going public. We use the number of firms already listed in CRSP in the same 3 digit SIC industry to proxy the ease of evaluation in an industry. The more firms already listed in the industry; in general, the easier it is for the investors to evaluate a firm in

¹⁹ As robustness check, we also use alternative measures of sales growth. We defined sales growth as the growth in firm sales over a one year period. We also defined sales growth as a dummy variable which equals one if the firm had a high growth rate. We define high growth rate if the average sales growth over the last 3 years was above 25%, with each year's growth being at least 10%. The results remain qualitatively unchanged.

²⁰ This definition is similar that in Loughran and Ritter (2002).

that particular industry. Therefore, this measure is expected to have a positive relationship with the probability of firm going public from that industry.

To test *H2*, we also construct information asymmetry measures using analysts' forecasts from I/B/E/S. Following Christie (1987) and Krishnaswamy and Subramaniam (1999), we use three different measures of information asymmetry. We use the industry average standard deviation in analysts' forecast (*STDEV*), the industry average analysts' forecast error (*FORERR*), and the industry average number of analysts following (*NUMA*) at the 3 digit SIC level. Higher standard deviation in analysts' forecast, higher analysts' forecast error, and fewer analysts following in an industry, proxy for higher information asymmetry in that industry. We expect higher information asymmetry to have a negative relationship with the probability of going public.

Table 2 presents the summary statistics of firm characteristics for the private firms which eventually go public during the sample period and also for the firms which remain private throughout the sample period in the LRD. All reported statistics are firm year observations. We see that the firms that eventually go public in our sample period are on average larger firms (about 6 times), and firms that are on average older. Moreover, firms that have an IPO, on average invest more (about 17%) than private firms. Also the average sales growth for IPO firms is 13.3% which is about 250% higher than the sales growth of firms remaining private. Finally, the *TFP* of IPO firms is on average 0.036, while that of private firms is -0.014. Thus, while the *TFP* of the firms going public is positive, implying that they perform better than their industry average, the *TFP* of the firms remaining private is negative and hence their performance is below that of their industry average.²¹

²¹ We also look at the summary statistics of the IPO sample only in the years prior to going public. The same trend is observed for nearly all the firm characteristics. These firms on average are larger, older and more productive than those which remain private. For example, the average sales growth for this sample is 12.9%; the average *TFP* is 0.042. Detailed results are available from the authors upon request.

4. Analysis of the Relationship between Product Market Characteristics and the Going Public Decision

In this section, we analyze the going public decision of firms. Using a large sample of private firms from the U.S. Census Bureau's LRD database, we look at the determinants of going public, with emphasis on the product market characteristics of the firm.

On the basis of the hypotheses developed in section 2.1, we estimate the following maximum likelihood probit model of the probability of going public. Individual firms are indexed i ; industries j ; for each year t , in the sample:²²

$$\begin{aligned} Pr(IPO_{ijt} = 1) = F(&\beta_1 SIZE_{i,t-1} + \beta_2 SGTH_{i,t-1} + \beta_3 MSHR_{i,t-1} + \beta_4 TFP_{i,t-1} + \beta_5 CAPINT_{i,t-1} \\ &+ \beta_6 AGE_{i,t-1} + \beta_7 CAPR_{i,t-1} + \beta_8 INDRSK_{j,t-1} + \beta_9 HI_{j,t-1} + \beta_{10} TOV_{j,t-1} + \beta_{11} HTEK_{i,t-1} \\ &+ \beta_{12} LIST_{j,t-1} + \beta_{13} STDEV_{j,t-1} + \beta_{14} FORERR_{j,t-1} + \beta_{15} NUMA_{j,t-1} + \beta_{16} SP500_{t-1}), \end{aligned} \quad (2)$$

where IPO is a dummy variable which equals 1 if the firm goes public in year t , and 0 if the firm remains private.²³ $F(\bullet)$ is the cumulative distribution function of a standard normal variable and $SP500$ is the annual return on Standard & Poor's 500 Index.²⁴ All other variables are as described in the previous section. At any time t , the sample includes all firms which are private at that point in time, and the firms which go public (had an IPO) in that year. After a firm goes public, that firm is dropped from the sample.

Table 3 presents the maximum likelihood estimates of the probit model. In panel A, the explanatory variables are limited to firm specific product market variables. In panel B, the firm specific product market variables are supplemented by industry specific variables. Finally, panel C

²² We also estimate a logit model for the same specification. The logit model gives the same qualitative results as the probit model. Hence, throughout the paper, we only report the results using the probit model.

²³ Note that for firms which remain private throughout, this dummy variable is always equal to zero.

²⁴ It is a well know stylized fact that the IPO market exhibits cyclical patterns over time. To control for this time varying effect of the equity market conditions, we use year dummies. Many theoretical and empirical papers argue that this cyclical pattern is partly due to overall market performance. Hence, in alternate specifications, we use the S&P500 annual return as a control. Note that, the year dummies perfectly capture the annual market performance component. Therefore, when we use year dummies as control, we do not use the S&P500 annual return.

includes information asymmetry proxies as well as the firm specific and industry specific variables of panels A and B. We can think of panel C as incorporating the entire regression model of the firm's decision to go public, as hypothesized in section 2.1.²⁵

From panel A, we can see that all the firm specific product market variables are significant determinants of the firm's decision to go public. Consistent with *H1*, *SIZE* has a positive effect on the probability of going public. In both specifications, the coefficients of *SIZE* are positive and significant at the 1% level. Consistent with *H8*, *TFP* has a positive effect on the probability of going public. In both specifications, the coefficients of *TFP* are also positive and significant at the 1% level. Consistent with *H9*, *CAPR* and *SGTH* both have positive effects on the probability of going public, and the coefficients on *CAPR* and *SGTH* across specifications are significant at the 1% level respectively. Consistent with *H5*, *MSHR* is positively related to the going public decision, and its coefficients are all positive and significant at the 1% level. In the second regression in panel A, we use the *SP500* variable to control for market fluctuations instead of year dummies. As expected, the coefficient on *SP500* is positive, implying that firms are more likely to go public after a positive market performance. The coefficient on *SP500* is significant at the 1% level. In summary, the results in panel A strongly support our hypotheses that larger, more productive firms, and firms with higher sales growth, higher capital expenditures, and bigger market shares have a higher probability of going public.²⁶

Panel B regressions includes industry specific characteristics such as industry risk, industry concentration, and the average share liquidity in the industry in addition to the firm specific product market variables in panel A. Comparing the regression 1 in panel B with regression 1 in panel A, we see that the coefficients on the firm specific product market variables have similar magnitudes, direction and significance, in both regressions. Moreover in panel B, all the three

²⁵ In all specifications, heteroskedasticity corrected standard errors are reported in parentheses.

²⁶ The coefficients in a probit regression are difficult to interpret directly. For example, the coefficient on *TFP* in regression 1, of 0.310 means that each one unit increase in *TFP*, increases the standard deviation of the probit index by 0.310. Similarly, for *SIZE* in regression 2, a one unit increase in *SIZE*, increases the standard deviation of the probit index by 0.209.

industry level explanatory variables (*INDRSK*, *HI*, *TOV*) are statistically positive and significant at the 1% level, and their directions are as predicted by the hypotheses (*H4*, *H6*, *H2*). Also, the introduction of industry level explanatory variables increases the explanatory power of the probit model. Regression 2 in panel B also includes the high tech dummy variable. The coefficient on the high tech dummy coefficient is positive, and significant at the 1% level. This is in contrast to our hypothesis *H7*, which predicts that firms in hi-tech industries are less likely to go public. Our empirical results however find that the probability of going public is significantly higher for those firms which operate in hi-tech industries.²⁷ Since the high tech dummy also captures some of the common characteristics across industries, the magnitude of the coefficients on the industry related measures (*MSHR*, *INDRSK*, *TOV*) are affected, even though the direction and significance of those coefficients remain similar (only the significance for *INDRSK* reduces from the 1% level to the 5% level).

Regression 3 in panel B shows the effect of *CAPINT* and *AGE*. Due to a multi-collinearity problem between *SIZE*, *CAPINT*, and *AGE*, we do not include *SIZE* as a control in this regression. Consistent with *H4*, the estimate on *CAPINT* is positive and significant at the 1% level, implying that more the capital intensive the firm the more likely it is to go public. Consistent with *HI*, the coefficient on *AGE* has the correct sign, but is not statistically significant in this specification.

The regressions in table 3 panel C include information asymmetry proxies along with the firm specific and industry specific variables from panels A and B. Regression 1 in panel C includes *LIST* as a proxy for the ease of evaluation in addition to all the variables in panel B regression 1. The coefficient on *LIST* is positive and significant at the 1% level. This is consistent with *H3* that firms operating in industries that are easier for public investors to evaluate are more likely to go

²⁷ One caveat of this result is that our hi-tech industries are all within the manufacturing sector. Thus, service oriented hi-tech industries, such as computer software is not included in our sample.

public. Regression 2 in panel C also includes *STDEV* as a proxy for information asymmetry.²⁸ Consistent with *H2*, the coefficient on *STDEV* in regression 2 is negative and statistically significant at the 10% level, which implies that higher the information asymmetry, less likely the firm goes public.

Regression 3 and 4 in panel C, support alternate the specifications with *SP500* and two measures (*STDEV*, *FORERR*) of information asymmetry respectively. In regression 3, we use *SP500* as a control for the market fluctuations instead of the year dummies. Consistent with our hypothesis, the coefficient on *SP500* is positive and significant at the 1% level, similar to that in panel A and panel B. Consistent with our hypothesis (*H2*) the results in regression 4 show that firms in industries with higher asymmetric information have a lower probability of going public. While the coefficient on *STDEV* is negative and significant, the coefficient on *FORERR* is negative but however insignificant.

Regressions 5 through 9 examine the effects of *CAPINT* and *AGE* along with the other explanatory variables as well as the information asymmetry proxies. The results are mostly consistent with our hypothesis as well as the results from the earlier specifications. Consistent with *H4*, the coefficients on *CAPINT* across the specifications are positive and significant at the 1% level. Consistent with *H1*, the coefficients on *AGE* are positive and significant at the 1% level in regressions 5 and 6; while in regressions 7 to 9, they are positive but however insignificant. Coefficients of the other variables follow the same pattern as before.

In summary, the regression results in table 3 are consistent with our hypotheses. We find that larger, older, more capital intensive firms, firms with higher total factor productivity, higher growth in output (sales), firms with high capital expenditure ratio, and firms with higher market share are more likely to go public. Firms operating in more concentrated industries, firms in more

²⁸ The information asymmetry proxies constructed from I/B/E/S only starts from 1976. Therefore, regressions in panel C that use the information asymmetry measure(s) are based on the sample in the period from 1976 to 2000 instead of the full sample.

risky industries, and firms in industries with higher liquidity and less asymmetric information are more likely to go public.

While some of our results agree with those in Pagano, Panetta, and Zingales (1998) and Helwege and Packer (2003), to the best of our knowledge our findings on total factor productivity, market share of the firm, industry risk and concentration, and industry liquidity and asymmetric information are completely new. This is the first paper in the literature which documents that TFP and market share of the firm are important determinants of the going public decision. A one unit increase in TFP leads to roughly a 7% increase in the sample average probability of an IPO. Similarly a one standard deviation increase in market share leads to an increase in the probability of going public, by one-fourth of a percentage point which corresponds to a 42% increase in the sample average probability of going public.

Similar to Pagano, Panetta, and Zingales (1998) and Helwege and Packer (2003), we show that size and capital expenditure are important determinants also. A unit increase in size leads to an increase in the sample average probability of an IPO by 4.25%; while a similar increase for capital expenditure increases the probability by 26.5%. Additionally we also show that sales growth is positively related to the going public decision. A unit increase in sales growth leads to roughly a 13% increase in the sample average probability of an IPO. Contrary to the results in Helwege and Packer (2003), but consistent with those of Boehmer and Ljungqvist (2001) (who study a sample of German IPO's), we document that more mature (older) firms have a higher probability of going public. A one unit increase leads to roughly a 7% increase in the sample average probability of an IPO.²⁹

As mentioned before, this is the first paper to show that industry risk and concentration, as well as industry liquidity and the level of asymmetric information in the industry have a significant

²⁹ Unlike Helwege and Packer (2003), our sample of private firms is the universe of all private manufacturing firms in the U.S., while the sample of private firms in Helwege and Packer (2003) are typically much older and larger private firms which have previously issued corporate debt. Thus, compared to their sample, our sample of private firms is much more representative of the U.S. economy.

impact on the probability of a firm going public. Firms in industries associated with higher risk, higher concentration, higher liquidity and less asymmetric information tend to go public earlier. These results are highly consistent with predictions of prior theoretical studies on IPO's, as outlined in section 2.1.

5. Analysis of the Dynamics of Firm Characteristics Before and After the IPO

In this section, we analyze the dynamic pattern of various firm specific product market characteristics around the IPO date. While there are empirical papers in the IPO literature (such as Jain and Kini (1994) and Mikkelson, Parch, and Shah (1997)) which look at the operating performance of IPO firms subsequent to the IPO, there has been no extensive study of firm performance in the years prior to the IPO. Using a unique sample of data from the LRD database of the U.S. Census Bureau, this paper, analyzes for the first time in the literature, the dynamic pattern of firm productivity and other product market firm characteristics from 5 years prior to the IPO to 5 years after the IPO.³⁰

Operating performance of firms after an IPO has been extensively studied in the existing empirical literature. However, mostly due to data limitations, firm performance prior to the IPO has been understudied. As discussed in section 2.2, there are various theories which provide interesting implications of firm dynamics around the IPO. In this section, we empirically investigate the dynamics of various firm characteristics before and after the IPO.

To study the dynamics of firm performance, we employ a regression framework of the following specification:

$$y_{it} = \alpha_t + \beta_i + \gamma X_{it} + \sum_{s=1}^5 \delta_s \text{Before}_{it}^s + \sum_{s=1}^5 \lambda_s \text{After}_{it}^s + \varepsilon_{it}, \quad (3)$$

³⁰ The results are robust to the choice of this 5 year windows on each side of the IPO. We obtain similar results when considering 7 year and 3 year windows also.

where Y_{it} is the variables of interest (e.g., TFP, sales, capital expenditures, etc.), X_{it} is a control for firm size which is time varying, $Before^s_{it}$ is a dummy variable equal to 1 if the firm goes public and the observation is s years prior to the IPO, where $s = 1, 2, 3, 4$, and 5 years and above, $After^s_{it}$ is a dummy variables equal to 1 if the firm goes public and the observation is s years after the IPO, where $s = 1, 2, 3, 4$, and 5 years and above, i indexes firms, t indexes years, and β_i are firm-specific effect. The specification also incorporates year dummies. The dynamic patterns of the effect of an IPO on the variables of interest are captured by the coefficients δ_s and λ_s .³¹

We first examine the dynamic patterns of TFP, sales and capital expenditures over five years before and after the IPO. Table 4 presents the regression results. While the results reported in panel A includes firms going public along with firms which remain private throughout our sample, panel B reports the results only for the subsample of the firms going public.³² Consistent with Clementi (2002), the TFP of firms going public exhibit an inverted U shape, which increases before the IPO, reaches its peak at the year of the IPO, and subsequently declines. Compared to the IPO year, in panel A, the coefficients on the all the *Before* and *After* dummies are negative, with the coefficients on $Before^{5+}$, $Before^4$, $Before^3$, and $Before^2$ being significant at the 1% level, and the coefficients on $After^3$ and $After^4$ significant at the 5% and the 10% level respectively. The changes in TFP in the years prior to going public are also very significant economically. The increase in TFP from year -2 to year -1 of 2.2%, translates to an increase in profits of approximately 13%. Similarly, the increase in TFP over the four years prior to going public, (i.e., from year -4 to 0) of 4.6% translates to an increase in profits of 28%.³³ In panel B, this pattern is even stronger. The increase in TFP from year -2 to -1 , corresponds to an increase of 13% in profits; from year -4 to 0,

³¹ In all the specifications, our base year is the year of the IPO (year 0). Thus the coefficients δ_s and λ_s reflects the deviations of the variable of interest with respect to the year of going public. In results not reported we also specify the year prior to the IPO year (year -1) as our base year. The results obtained are consistent with those reported here.

³² In results not reported, we also look at the dynamic pattern of firm characteristics of the firms going public along with those which have already gone public previously. The results obtained are consistent with those presented here.

³³ For a detailed explanation of the relation between TFP and profits see Schoar (2002). The calculations presented above assume a revenue margin of 20% over costs.

an increase of 23% in profits; from year 0 to 2, a decrease of 10% in profits; and from year 0 to 4, a decrease of 16% in profits.

The coefficients on sales keep increasing throughout the years. In panel A, all the coefficients on the *Before* dummies are negative and significant at the 1% level, while all the coefficients on the *After* dummies are positive, with the *After*¹ coefficient significant at the 5% level and the *After*² through *After*⁵ coefficients being significant at the 1% level. The result implies that the IPO firms are growing over the years around the IPO compared to their private peers. The result on capital expenditures in panel A shows similar increasing patterns as sales, with all the coefficients on the *Before* dummies negative and significant at the 1% level, while all the coefficients on the *After* dummies being positive, with the *After*⁴ coefficient significant at the 10% level and other *After* dummy coefficients significant at the 1% level. When the regression is restricted to the sample of the going public firms (panel B), the increasing pattern of sales and capital expenditures after IPO is weak, after controlling for the growth in size of IPO firms. This means that for a unit increase in size, the sales and capital expenditures of IPO firms grow faster than that of the private firms.

We examine the dynamic pattern of total employment, labor costs and other costs in table 5. Panel A in table 5 shows that total employment, total wages, material costs, and rental and administrative expenses all increase over the years around IPO, with all the coefficients on the *Before* dummies being negative, and all the coefficients on the *After* dummies being positive. Other than the years immediately before and after the IPO, the coefficients on other years are significant at the 1% level. These results again show that the rates of growth of these costs in IPO firms are faster compared to the firms remaining private. In panel B of table 5, when we restrict the sample to only the IPO firms, the results seem to suggest that the increase in total employment, total wages, material cost, and rental and administrative expenses around the years before and after the IPO are mostly proportional to the firms' growth in size. However, in years -3 and -2, there

seems to be an additional surge in employment and administrative expenses, which could be due to the sudden increase in the firm's scale of operations, as suggested by the theoretical literature.

Finally, in table 6 we examine two sales related variables, sales growth and market share. In table 4 we have already shown that sales of IPO firms grow throughout the years around the IPO. The result on sales growth in table 6, shows that all the *Before* and *After* coefficients are negative, implying that sales growth reaches its peak at the year of the IPO. Other than the one year immediately before and after the IPO, the coefficients on all the other years are significant at the 1% level. Thus consistent with our hypothesis, we find that sales growth of IPO firms exhibit an inverted U shape. This pattern holds in both panel A and panel B of table 6. As discussed in section 2.2, we were agnostic about the dynamic pattern of market share. The results both in panels A and B of table 6 shows market share remains flat after adjusting for firm size over the 9 year horizon around the IPO. The coefficients on the *Before* and *After* dummies are statistically insignificant most times.

Thus the results on the dynamic pattern of firm characteristics are mostly consistent with our predictions from section 2.2. While, TFP and sales growth both depict an inverted U shape, implying that they reach their peak in the year of going public; sales, capital expenditures and various costs associated with the product and labor markets show gradually increasing pattern from 5 years prior to the IPO to 5 years subsequent to the IPO when compared to their private peers.

6. Conclusion

We use a large and representative sample of U.S. manufacturing firms to study two related questions regarding the going public decisions of private firms. In the first part of the paper, we study the relationship between a firm's *ex ante* product market characteristics and its decision to go public. In the second part of the paper, we study the dynamics of a firm's product market performance for a number of years before and after it goes public. Our findings are as follows. First, firms with larger size, sales growth, total factor productivity (TFP), market share, and capital

intensity are more likely to go public. Second, firms operating in less competitive and more capital intensive industries, and those in industries characterized by riskier cash flows, are more likely to go public. Third, firms with projects that are cheaper for outsiders to evaluate, and operating in industries characterized by less information asymmetry and greater average liquidity of already listed equity are more likely to go public. Our analysis of the dynamic pattern of firm performance around the IPO indicates that while TFP and sales growth exhibit an inverted-U shaped pattern (with peak productivity and sales growth occurring in the year of IPO), sales, capital expenditures, employment, total labor costs, materials costs, and selling and administrative expenses exhibit a consistently increasing pattern in the years before and after the IPO.

Table 1: Industry Distribution of the Going Public Sample: This table presents the 2 digit level SIC industry distribution of the sample of manufacturing firms in the LRD which eventually went public during the period of 1972 to 2000. ND stands for Not Disclosed to comply with the U.S. Census Bureau's disclosure criteria.

<u>2 Digit SIC</u>	<u>Industry Name</u>	<u>Number of IPO Firms</u>
20	Food and kindred products	50
21	Tobacco products	ND
22	Textile mill products	34
23	Apparel and other textile products	37
24	Lumber and wood products	27
25	Furniture and fixtures	24
26	Paper and allied products	24
27	Printing and publishing	43
28	Chemicals and allied products	83
29	Petroleum and coal products	ND
30	Rubber and miscellaneous plastics products	47
31	Leather and leather products	ND
32	Stone, clay, and glass products	34
33	Primary metal industries	110
34	Fabricated metal products	47
35	Industrial machinery and equipment	201
36	Electronic and other electric equipment	245
37	Transportation equipment	53
38	Instruments and related products	187
39	Miscellaneous manufacturing industries	ND

Table 2: Summary Statistics: This table presents summary statistics for firms eventually going public and private firms in the LRD between 1972 and 2000. The firms eventually going public are those firms in the manufacturing sector (SIC 2000-3999) that went public between 1972 and 2000 as recorded from SDC. The firms remaining private are all the firms in the LRD which did not have an IPO between 1972 and 2000, and which were not public prior to 1972. Size is the natural logarithm of firm capital stock (in thousands of dollars). Capital Stock is constructed via the perpetual inventory method and is the sum of building assets *plus* machinery assets. Sales is the total value of shipments in thousands of dollars. Market share is the firm's market share in terms of sales in the same 3 digit SIC industry. Capital Expenditure is the sum of new and used capital expenditures by the firms (in thousands of dollars). Capital Expenditure Ratio is capital expenditure over capital stock. Age is the number of years since the firm first appeared in the LRD sample. Capital intensity is the capital stock over total employment. TFP is the weighted average of plant level Total Factor Productivity at the four digit SIC level. To calculate TFP one regresses the value of output (total value of shipments adjusted for changes in inventories) on labor (production worker equivalent man hours), capital stock, and material inputs (intermediate inputs, fuels, and energy consumed). Sales growth is the average growth in sales in the past three years. Percentage of Hitech is the percentage of firms in the sample that are high tech companies (i.e., belonging to 3 digit SIC codes 357, 366, 367, 372, 381, 382, 384). Total wage is sum of total salaries and wages of the firm in thousands of dollars. Average wage is total wage over total employment. Material Cost is the expenses for the cost of materials and parts purchased, resales, contract work, and fuel and energy purchased, in thousands of dollars. Rental and Administrative Expenses is the rental payments or equivalent charges made during the year for the use of buildings, structures, and various office equipments, in thousands of dollars. All the dollar values are in real terms. All the observations are firm year observations.

Sample:	<u>Firms Eventually Going Public</u>			<u>Firms Remaining Private</u>		
	Mean	Std. Dev.	Obs.	Mean	Std. Dev.	Obs.
Capital Stock	30637	41161	13,296	4168	13977	916,031
Total Employment	777	805	13,270	132	292	916,106
Sales	108141	124449	13,214	14828	41322	907,109
Market Share	0.022	0.061	14,383	0.002	0.014	914,928
Capital Expenditure	3484	4401	13,222	457	1498	915,900
Capital Expenditure Ratio	0.143	0.146	12,877	0.122	0.179	677,601
Age	9.473	7.300	14,386	5.178	5.652	918,445

TFP	0.036	0.219	13,792	-0.014	0.207	851,555
Sales Growth	0.133	0.325	12,646	0.038	0.356	637,287
Percentage of Hi-tech	0.282	0.450	14,386	0.049	0.215	918,445
Total Wage	22120	23377	13,196	3366	8125	916,188
Average Wage	29.798	9.689	13,867	24.232	9.727	864,986
Material Cost	103962	163221	14,386	10512	42367	918,445
Rental and Admin. Exp.	4449	4959	13,241	650	1706	916,213

Table 3: Determinants of the Going Public Decision: This table presents the effects of firm specific product market variables, industry specific characteristics and asymmetric information on firm's decision to go public. The effect of the variables on the probability of going public is estimated by the following probit model. $Pr(IPO_{ijt} = 1) = F(\beta_1 SIZE_{i,t-1} + \beta_2 SGTH_{i,t-1} + \beta_3 MSHR_{i,t-1} + \beta_4 TFP_{i,t-1} + \beta_5 CAPINT_{i,t-1} + \beta_6 AGE_{i,t-1} + \beta_7 CAPR_{i,t-1} + \beta_8 INDRSK_{j,t-1} + \beta_9 HI_{j,t-1} + \beta_{10} TOV_{j,t-1} + \beta_{11} HTEK_{i,t-1} + \beta_{12} LIST_{j,t-1} + \beta_{13} STDEV_{j,t-1} + \beta_{14} FORERR_{j,t-1} + \beta_{15} NUMA_{j,t-1} + \beta_{16} SP500_{t-1})$ where $F(\cdot)$ is the cumulative distribution function of a standard normal variable. The dependent variable is 0 if the firm is private and 1 on the year of the IPO. Note that the sample does not contain any existing public firms. *SIZE* is the lagged value of logarithm of capital stock. *SGTH* is the average growth in sales in the past 3 years. *MSHR* is the lagged value of a firm's market share in terms of total value of shipment in its 3 digit SIC industry. *TFP* is the lagged value of weighted average of plant level Total Factor Productivity at the four digit SIC level, where one regresses the value of output (total value of shipments adjusted for changes in inventories) on labor (production worker equivalent man hours), capital stock, and material inputs (intermediate inputs, fuels, and energy consumed). *CAPINT* is the lagged value of capital stock per worker. *AGE* is the natural logarithm of firm age. *CAPR* is the lagged value of capital expenditures over capital stock. *HTEK* dummy is 1 if the firm is in the 3 digit SIC code of 357, 366, 367, 372, 381, 382, 384, and 0 otherwise. *INDRSK* is the median of the 5 year standard deviation in sales at the SIC 3 digit industry level of all the firms covered in the LRD that year. It is also lagged by one year. *HI* is the lagged value of Herfindal Index in the 3 digit SIC industry level. The higher the Herfindal Index, the more concentrated the industry is. *LIST* is the total number of firms in the same 3 digit SIC industry that are listed in the CRSP in the last year. *TOV* is the mean of stock turnover (calculated as trading volume over total number of shares outstanding) at the 3 digit SIC level in the last year. *NUMA* is the 3 digit SIC industry level mean of the number of analysts covering firms in an industry. *FORERR* is the 3 digit SIC level mean of average analysts forecast errors across firms in the industry. *STDEV* is the 3 digit SIC level mean of the standard deviation in Analysts Forecast of EPS. *NUMA*, *FORERR*, and *STDEV* are all measured from I/B/E/S and the observations are lagged by a year. *SP500* is the last year's annual return of the Standard & Poor's 500 index. All dollar values are in real terms. All observations are firm year observations. Panel A presents results on the effects of firm specific product market variables on the firm's decision to go public. Panel B presents the effect of firm specific variables along with industry specific characteristics on the firm's decision to go public. Panel C presents the effect of firm specific variables along with industry specific characteristics and asymmetric information variables on firm's decision to go public. Calendar year dummies are included in the regressions when year dummies is specified as yes. Heteroskedasticity corrected robust standard errors are in parentheses. ***, **, and * indicate significance at the 1, 5, and 10 percent level respectively.

Table 4: Dynamic Characteristics of TFP, Sales, and Capital Expenditure around the IPO: This table presents the dynamic pattern of TFP, Sales, and Capital Expenditure before and after the going public event. TFP is the weighted average of plant level Total Factor Productivity at the four digit SIC level, where one regresses the value of output (total value of shipments adjusted for changes in inventories) on labor (production worker equivalent man hours), capital stock, and material inputs (intermediate inputs, fuels, and energy consumed). Sales is the total value of shipments in thousands of dollars. Capital Expenditure is the dollar value of capital expenditure by the firms, in thousands of dollars. The control variable Size is the natural logarithm of firm capital stock, where capital stock is constructed via the perpetual inventory method and is the sum of building assets *plus* machinery assets in thousands of dollars. All the *Before* and *After* variables with superscripts are dummy variables. *Before*⁵⁺ equals 1 for five years and more before the firm goes public, and 0 otherwise. *Before*⁴, *Before*³, *Before*², *Before*¹ equals 1 for 4, 3, 2, 1 year(s) before the firm goes public respectively, and 0 otherwise. Similarly, *After*¹, *After*², *After*³, *After*⁴ equals 1 for 1, 2, 3, 4 year(s) after the firm goes public respectively, and 0 otherwise. *After*⁵⁺ equals 1 for five years and more after the firm goes public, and 0 otherwise. All dollar values are in real terms. All observations are firm year observations. Panel A regressions are based on all the firm year observations in the LRD for the firms eventually going public along with the firms remaining private. Panel B regressions are restricted to all the firm year observations in the LRD for the firms eventually going public. The following panel regression is estimated in all the specifications: $Y_{it} = \alpha_i + \beta_i + \gamma X_{it} + \sum_{s=1}^5 \delta_s Before_{it}^s + \sum_{s=1}^5 \lambda_s After_{it}^s + \varepsilon_{it}$. All the regressions are ordinary least square regressions with firm fixed effect and calendar year dummies. Heteroskedasticity corrected robust standard errors are in parentheses. ***, **, and * indicate significance at the 1, 5, and 10 percent level respectively.

Table 5: Dynamic Characteristics of Firm Employment, Labor and Other Costs around the

IPO: This table presents the dynamic pattern of Employment, Total Wage, Materials cost, and Rental and Administrative Expenses before and after the going public event. Total employment is the total number of employees in the firm. Total wage is the total payroll of the firm in thousands dollar unit. Material Cost is the expenses for the cost of materials and parts purchased, resales, contract work, and fuel and energy purchased, in thousands of dollars. Rental and Administrative Expenses is the rental payments or equivalent charges made during the year for the use of buildings, structures, and various office equipments, in thousands of dollars. The control variable Size is the natural logarithm of firm capital stock, where capital stock is constructed via the perpetual inventory method and is the sum of building assets *plus* machinery assets in thousands of dollars. All the *Before* and *After* variables with superscripts are dummy variables. *Before*⁵⁺ equals 1 for five years and more before the firm goes public, and 0 otherwise. *Before*⁴, *Before*³, *Before*², *Before*¹ equals 1 for 4, 3, 2, 1 year(s) before the firm goes public respectively, and 0 otherwise. Similarly, *After*¹, *After*², *After*³, *After*⁴ equals 1 for 1, 2, 3, 4 year(s) after the firm goes public respectively, and 0 otherwise. *After*⁵⁺ equals 1 for five years and more after the firm goes public, and 0 otherwise. All dollar values are in real terms. All observations are firm year observations. Panel A regressions are based on all the firm year observations in the LRD for the firms eventually going public along with the firms remaining private. Panel B regressions are restricted to all the firm year observations in the LRD for the firms eventually going public. The following panel regression is estimated in all the specifications:
$$Y_{it} = \alpha_i + \beta_i + \gamma X_{it} + \sum_{s=1}^5 \delta_s Before_{it}^s + \sum_{s=1}^5 \lambda_s After_{it}^s + \varepsilon_{it}$$

All the regressions are ordinary least square regressions with firm fixed effect and calendar year dummies. Heteroskedasticity corrected robust standard errors are in parentheses. ***, **, and * indicate significance at the 1, 5, and 10 percent level respectively.

Table 6: Dynamic Characteristics of Firm Sales Growth and Market Share around the

IPO: This table presents the dynamic pattern of Sales growth and Market share of the firm before and after the going public event. Sales growth is the average growth in sales in the past three years. Market share is the firm's market share in terms of sales in the same 3 digit SIC industry. The control variable Size is the natural logarithm of firm capital stock, where capital stock is constructed via the perpetual inventory method and is the sum of building assets *plus* machinery assets in thousands of dollars. All the *Before* and *After* variables with superscripts are dummy variables. $Before^{5+}$ equals 1 for five years and more before the firm goes public, and 0 otherwise. $Before^4$, $Before^3$, $Before^2$, $Before^1$ equals 1 for 4, 3, 2, 1 year(s) before the firm goes public respectively, and 0 otherwise. Similarly, $After^1$, $After^2$, $After^3$, $After^4$ equals 1 for 1, 2, 3, 4 year(s) after the firm goes public respectively, and 0 otherwise. $After^{5+}$ equals 1 for five years and more after the firm goes public, and 0 otherwise. All dollar values are in real terms. All observations are firm year observations. Panel A regressions are based on all the firm year observations in the LRD for the firms eventually going public along with the firms remaining private. Panel B regressions are restricted to all the firm year observations in the LRD for the firms eventually going public. The following panel regression is estimated in all the specifications: $Y_{it} = \alpha_i + \beta_i + \gamma X_{it} + \sum_{s=1}^5 \delta_s Before_{it}^s + \sum_{s=1}^5 \lambda_s After_{it}^s + \varepsilon_{it}$. All the regressions are ordinary least square regressions with firm fixed effect and calendar year dummies. Heteroskedasticity corrected robust standard errors are in parentheses. ***, **, and * indicate significance at the 1, 5, and 10 percent level respectively.
