# A Theory of Good Intentions\*

Paul Niehaus UC San Diego & NBER

September 13, 2017

#### Abstract

Altruists often seem to produce results that fall short of their intentions. I examine this tension in a model where altruists derive warm glow from their *perceptions*, as opposed to actual outcomes. Perceptions and reality can diverge when feedback is incomplete: a donor to an international development project, for example, may not learn about the results. I find that, to the extent feedback is incomplete, well-intentioned altruists avoid information before deciding how to act. Incentives for intermediaries such as charities to generate information are limited and contingent on donor motivations. This suggests a role for policy—yet policy-makers are themselves constrained by a tradeoff between the quantity and quality of altruistic behavior.

<sup>\*</sup>I thank Nageeb Ali, Jim Andreoni, Navin Kartik, Joel Sobel, Adam Szeidl, Lise Vesterlund, and seminar participants at Microsoft Research New England, Columbia, UCLA, NEUDC, and the Duke Mini-conference on Charitable Giving for helpful comments. Microsoft Research New England provided generous hospitality.

# 1 Introduction

Altruists often seem to produce results that fall short of their intentions. This perception is so widespread that the term "well-intentioned" has become a euphemism for "poorly informed." Consider charitable giving, for example: Americans give about 2% of GDP to charity each year, suggesting they care deeply about others, yet only 3% of donors even *claim* to have done any research comparing the effectiveness of alternatives. Such figures beg the question: if people really are well-intentioned, why don't they *become* well-informed?

Economists have generally taken the view that they want to, but find it costly or difficult. Krasteva and Yildirim (2013) emphasize that the costs of learning may exceed the benefits in the context of small charitable donations. In international development, market failures are seen as a major culprit: information about effectiveness is a public good (Duflo and Kremer, 2003; Levine, 2006; Ravallion, 2009), and communication from practitioners to funders is often distorted by strategic considerations (Pritchett, 2002; Duflo and Kremer, 2003; Levine, 2006). Institutions such as J-PAL, IPA, and CEGA were created in part to address such concerns.

I examine an alternative (and complementary) interpretation: altruists do not want to achieve a better outcome. Instead, they want to believe they have done so. This creates tension in settings where perception and reality can easily diverge. Consider, for example, making a donation to help feed malnourished African children. Thinking about those children eating generates a "warm glow" (Andreoni, 1989). Now suppose that your donation was wasted or stolen. Knowing this would presumably dampen the glow. Yet if you did not know, you would experience warm glow thinking about your impact even though in reality no such impact existed. This illustrates the mechanical fact that the preferences motivating your gift cannot literally have been over children's outcomes, which occur far outside of your experience. Instead, perceptions count.

This paper studies how learning works in a market where perceptions are the product. It focuses on a single benefactor and beneficiary, thus abstracting from issues of public goods. The benefactors' preferences with respect to the beneficiary may take any form, ranging from the classic case of "pure" altruism to more paternalist forms of other-regard. There is uncertainty in that the benefactor does not know ex ante how his decisions will affect the beneficiary ex post. The unusual feature of the model is that this uncertainty persists ex post with positive probability. As a result the benefactor may face residual ambiguity which he must interpret. For example, a donor may receive no news about whether the charity he gave to was effective and have to decide what this implies. He cannot learn the correct interpretation through repeated experience, precisely because the true state remains unobserved. I therefore consider the case where he interprets the evidence in the way maximizes his expected utility. This approach builds on evidence from psychology and economics that people tend to interpret

<sup>&</sup>lt;sup>1</sup>Giving statistics: author's calculation using data from The Giving Institute (2013) and the Bureau of Economic Analysis (http://www.bea.gov/national/index.htm#gdp, accessed 7 August 2013). Research statistics: see Hope Consulting (2012). The Hope sample over-represents wealthier donors and thus if anything likely overstates the amount of research done by the average donor.

<sup>&</sup>lt;sup>2</sup>This includes, for example, the impact philanthropy framework of Duncan (2004) as well as a class of models that capture "guilty" motives for giving, as suggested by Andreoni et al. (2012).

information in a self-serving manner.<sup>3</sup>

The beliefs that result have an innocuous structure: they are (endogenously) Bayesian and consistent with the distribution of observable data, and hence not falsifiable without ancillary data. For example, a well-intentioned donor correctly forecasts the probability that he will hear bad news about the cause he supported. On learning nothing, however, the donor assumes that "no news is good news" and views the cause as definitely effective. Because this effect appears only in the presence of ambiguity, the model predicts relatively normal behavior when outcomes are easily observable (such as helping a neighbor) but relatively distorted behavior when outcomes are unobserved (such as helping internationally).

The well-intentioned benefactor has a nuanced interest in learning. Specifically, he values information that helps him predict the feedback he will receive ex post, but otherwise prefers to avoid information. To understand this, note first that he seeks to avoid ex post feedback entirely for the simple reason that it constrains his beliefs. A donor who learns that his donation was stolen, for example, finds it harder to believe that it was effective. The key to making a good ex ante decision is therefore to anticipate any such news and avoid being disappointed by it. Before donating, for example, a donor would like to know whether an unpleasant scandal will later break. If not, however, he is otherwise happy to remain ignorant.

Of course, altruists often interact in the marketplace with intermediaries such as charities that have an incentive to persuade them to be generous. Might these intermediaries have an incentive to better educate well-intentioned donors? I examine how the expected revenue of an intermediary depends on their information-generating strategy – for example, whether they commission impact evaluations or measure the neediness of recipients. In some cases this unambiguously decreases revenue. For example, consider an "impact philanthropist" (Duncan, 2004) who wants to believe they are "making a difference" in the world. Such a donor already has strong incentives to believe that the need is great and that the charity to which they are donating is highly impactful; a charity can thus only demotivate him by generating information that could contradict these beliefs.

In other cases the optimal strategy for intermediaries is more nuanced. If a donor is a "pure altruist," for example, charities should optimally generate information about need (since the donor will otherwise want to convince herself that the need is not that great) but should not generate information about effectiveness (since the donor will otherwise convince herself that the charity is effective). This may help explain nonprofit marketing strategies that emphasize "awareness-raising" and graphic depictions of need ("poverty pornography") as opposed to evidence of cost-effectiveness. Overall, the limited incentives intermediaries have to generate useful information – and in particular information about impact – is consistent with the fact that charities provide little of this information themselves.<sup>45</sup>

<sup>&</sup>lt;sup>3</sup>See Benabou and Tirole (2016) for an overview and Eil and Rao (2011) and Mobius et al. (2013) specifically for laboratory evidence.

<sup>&</sup>lt;sup>4</sup>Charity evaluator GiveWell concludes, for example, that "useful information about what different charities do and whether it works isn't publicly available anywhere." http://www.givewell.org/about/story, accessed 10 September 2013.

<sup>&</sup>lt;sup>5</sup>Because it emphasizes the idea that donors care about their thoughts (as opposed to actual outcomes), the model is also well-suited to explaining a range of charitable marketing practices that seek to make gifts more memorable. These include both explicit reminders of past gifts and also the common practice of encouraging

The limited demand for and supply of information could potentially create scope for a third party to intervene and increase beneficiary welfare. For example, a government or private foundation might seek to counteract wishful thinking by subsidizing rigorous evaluations and the dissemination of their results. This can backfire, however, because of an inherent tradeoff in the model between the *quality* and the *quantity* of giving. Wishful thinking may indeed cause altruists to give to relatively ineffective causes – a new approach to poverty reduction with little concrete evidence to back it may capture their imagination, for example, and attract large sums. But disillusioning them may reduce the amount they give by so much as to be welfare-reducing, even if it redirects funds to more effective intermediaries. The same obviously applies to beneficiaries themselves: it is sometimes better not to look a gift horse in the mouth.

The model's key predictions are consistent with recent experimental evidence on gift-giving in the lab. First, there is evidence that subjects prefer to avoid ex-post feedback. Dana et al. (2007) find, for example, that only 56% of dictators choose to observe *free* information on the relationship between their actions and the recipient's payoffs; Fong and Oberholzer-Gee (2011) who find low willingness to pay for information about recipient identify, while Grossman and van der Weele (2013) find willingness to pay for ignorance. Second, there is evidence that greater ex-post feedback increases ex ante efforts to learn. Jhunjhunwala (2017) finds that subjects devote more effort to learning about alternative charities before donating when they know that they will subsequently be presented with a ranking of these charities. This is striking since, if subjects cared solely about actual outcomes, this intervention should have no impact on their search behavior.

Outside of the lab experimental control is of course reduced, but as noted above the data suggest that individual donors overwhelmingly choose not to research alternatives. Respondents in the Hope Consulting study told interviewers, for example, that "with known nonprofits, unless there is a scandal, you assume they are doing well with your money" (p. 38) and that "I don't research, but I am sure that the nonprofits to which I donate are doing a great job" (p. 42).<sup>6</sup> The model may also help explain the quality of personal gift-giving; Waldfogel (2009) estimates, for example, that holiday gifts are so poorly chosen that in many cases it would be better not to buy them.<sup>7</sup>

Some observers see good intentions as an issue in the institutional aid industry. Easterly (2006) emphasizes the role played by faith and desire: "I feel like kind of a Scrooge... I speak to many audiences of good-hearted believers in the power of Big Western Plans to help the poor, and I would so much like to believe them myself" [emphasis added]. No doubt this desire is only part of the story, alongside political and organization forces that affect the creation and use of information.<sup>8</sup> But it is consistent with the idea that there is something

donors to think of those gifts as memorable items (e.g. cows, sponsoring a specific child) even when they are in fact fungible.

<sup>&</sup>lt;sup>6</sup>Citing these data, the Hewlett Foundation recently ended an 8-year, \$12M initiative to promote evidence-based giving, saying that "the initiative assumed that donors would use this information if they could find it... [but] most donors aren't even looking." Video interview with Lucy Bernholz, http://www.hewlett.org/programs/effective-philanthropy-group, accessed 18 May 2014.

<sup>&</sup>lt;sup>7</sup>Unwanted Christmas gifts are so common that there are websites devoted to displaying bad examples: knick-knacks, ugly sweaters, and so on (see www.badgiftemporium.com or whydidyoubuymethat.com).

<sup>&</sup>lt;sup>8</sup>Industry veterans often lament the historically limited role of evidence in aid decision-making. Pritchett

fundamentally different about spending money on others' behalf. It may help explain why a new approach such as micro-lending can capture the imagination of practitioners and grow into a large industry before any rigorous evidence of its impact is available (Duflo et al., 2013). The model predicts that this is most likely precisely when little research exists to check the imagination.<sup>9</sup>

Conceptually the paper draws on and extends three strands of theoretical research. First, it takes very literally Andreoni's (1989) influential idea that altruists benefit from the "warm glow" that their acts induce. Andreoni has emphasized that "the warm-glow hypothesis simply provides a direction for research rather than an answer to the puzzle of why people give – the concept of warm-glow is a placeholder for more specific models of individual and social motivations" (Andreoni et al., 2012). The present paper offers one such model linking warm glow to perceived outcomes.

Second, it adds to the growing body of work in economics on motivated reasoning (Benabou and Tirole, 2016). This literature has focused primarily on self-regarding motives such as the desire to believe oneself competent, while I focus here on other-regard. Technically the model is most closely related to Brunnermeier and Parker's (2005) theory of optimal expectations, with the key difference that the decision-maker gets no utility from anticipation or remembrance and thus faces no tradeoff between anticipatory and flow utility. Instead his *sole* objective is to hold pleasant thoughts. As a result he exhibits no cognitive dissonance – that is, no desire to hold beliefs other than those he holds in "equilibrium."

Third, it offers an alternative view of persuasive activity. Economists have shown how persuasion is possible when a sender can exploit information asymmetries (e.g. Crawford and Sobel (1982)) or non-linearities in the receiver's mapping from beliefs to actions (e.g. Kamenica and Gentzkow (2011)). In this model persuasive marketing is possible without either of these mechanisms. Here, persuasion works by catering to the receiver's (predictably) wishful thinking. Wishful beliefs that serve the sender's interests are left alone, while those that harm his interests are confronted with data.

The rest of the paper is organized as follows. Section 2 presents the framework and characterizes optimal interpretations. Section 3 expresses the main ideas of the paper in the context of a simple example, which Section 4 then generalizes. Section 5 discusses outstanding questions.

# 2 The Framework

#### 2.1 Timing

There are two players, a benefactor and a beneficiary. Play evolves as follows:

- 1. Nature determines the value of a finite-valued parameter  $\theta \in \Theta$
- 2. A signal  $s_1 \in S_1$  is revealed and the benefactor forms subjective ex ante beliefs  $\hat{\pi}_1(\theta, s_2|s_1)$

<sup>(2002)</sup> describes the process as "ignorant armies clashing by night," with "very rarely any firm evidence presented and considered about the likely impact of... proposed actions."

<sup>&</sup>lt;sup>9</sup>On this note see Brigham et al. (2013) who find, intriguingly, that micro-finance institutions were unlikely to respond to emails mentioning research that microfinance was ineffective, but significantly more likely to respond to emails that mentioned positive results.

- 3. The benefactor chooses a decision  $d \in D$
- 4. A signal  $s_2 \in S_2$  is revealed and the benefactor forms subjective ex post beliefs  $\hat{\pi}_2(\theta|d, s_2, s_1)$
- 5. Payoffs are realized

Let  $\pi(\theta, s_2, s_1)$  be the joint distribution of the observable data  $(s_1, s_2)$  and the unobservable parameter  $\theta$ . The marginal distribution  $\pi(s_2, s_1|\theta)$  is fixed for now but will later be endogenized to characterize incentives for learning and communication. For brevity, let  $\hat{\pi} = (\hat{\pi}_1(\theta, s_2|s_1), \hat{\pi}_2(\theta|d, s_2, s_1))$  refer to the complete contingent belief profile.

#### 2.2 Payoffs

The beneficiary's payoff  $w(d, \theta)$  depends on the decision d and state  $\theta$ . The benefactor's payoff depends on two components: a purely self-interested component u(d), and an other-regarding component  $v(d, \theta)$  which represents the utility the benefactor obtains from the beneficiary's outcome(s). If the benefactor were perfectly informed about these outcomes, his payoff would be

$$u(d) + v(d, \theta) \tag{1a}$$

This specification implies, however, that the benefactor is *aware* of the ex-post realization of  $\theta$ . To capture situations in which this is unrealistic, I allow the benefactor's payoff to depend on his perception of  $\theta$ :

$$u(d) + \mathbb{E}_{\hat{\pi}_2}[v(d,\theta)] \tag{1b}$$

The fact that  $\hat{\pi}$  may be non-degenerate embodies the idea that uncertainty about  $\theta$  may not completely resolve by the end of the game.

Equation (1b) models altruism quite generally, in the sense that the beneficiary's preferences  $w(\cdot,\cdot)$  and the benefactors preferences for her  $v(\cdot,\cdot)$  can be arbitrarily related to each other. In the familiar case of pure altruism, v=w, so that – conditional on the level of u – the benefactor uses the same criteria to assess the beneficiary's well-being as the beneficiary himself. Alternatively, the benefactor might have paternalistic preferences (Garfinkel, 1973). Duncan (2004) has argued that some altruists care about their impact, defined as the difference between the payoff the beneficiary realizes and the counterfactual payoff they would have realized without the benefactor's help. If we define  $\bar{d} = \arg\max_d u(d)$  as the counterfactual action, then an impact philanthropist is defined by

$$v(d,\theta) = w(d,\theta) - w(\overline{d},\theta) \tag{2}$$

Another motive of interest is guilt, which recent studies have argued is important for many charitable donors (Andreoni et al., 2012). If we think of guilt as the desire to reduce the gap between what one is doing and what one *could* or *should* do, then we can represent guilty preferences again using (2) but defining the reference action  $\bar{d}$  as the one that *should* have been taken.<sup>10</sup>

<sup>&</sup>lt;sup>10</sup>Equation (1b) could even capture misanthropy, e.g. v = -w.

## 2.3 Optimization

Given beliefs, the benefactor chooses d to maximize his subjective expected utility:

$$d^*(\hat{\pi}, s_1) = \arg\max \mathbb{E}_{\hat{\pi}_1}[u(d) + v(d, \theta)] \tag{3}$$

Given this decision rule, the benefactor similarly chooses beliefs from an admissible set  $\Pi$  (defined below) to maximize his subjected expected utility:

$$\hat{\pi}^* = \arg \max_{\hat{\pi} \in \Pi} \mathbb{E}_{\pi} \left[ u(d^*(\hat{\pi}, s_1)) + \mathbb{E}_{\hat{\pi}_2} [v(d^*(\hat{\pi}, s_1), \theta)] \right]$$
(4)

If all beliefs were admissible then the model would be uninteresting: the benefactor would always choose to hold the rosiest beliefs possible, and would be complete unresponsive to (and thus uninterested in) information. This is because – unlike in Brunnermeier and Parker (2005) – there is no tradeoff between pleasant perceptions and ultimate realizations; here, perceptions are the only reality. The model is interesting if there are constraints on the benefactor's wishful thinking. I examine the following simple case:

**Assumption 1** (Admissible beliefs). Subjective beliefs  $\hat{\pi}_1(\theta, s_2|s_1)$  satisfy

- (a)  $\hat{\pi}_1(\theta, s_2|s_1)$  is a probability measure on  $\Theta \times S_2$  for any  $s_1$
- (b)  $\hat{\pi}_1(\theta, s_2|s_1) = 0$  if  $\pi(\theta, s_2|s_1) = 0$  for any  $(\theta, s_2, s_1)$

Subjective beliefs  $\hat{\pi}_2(\theta|d, s_2, s_1)$  satisfy analogous conditions.

Part (a) simply says that beliefs are well-defined. Part (b) is substantive and imposes a degree of logical consistency: the benefactor understands that some compound events are impossible and does not hold beliefs that are clearly incompatible with the facts. This is an extreme, dichotomic form of the more general idea that there are higher cognitive costs to convincing oneself of things that are less plausible given the data.

#### 2.4 Interpretation & Discussion

The framework above departs from standard approaches in two ways. First, the benefactor holds preferences over beliefs as well as over outcomes. This idea builds on a literature dating at least as far back as Akerlof and Dickens (1982), who model a employee who prefers to believe that his risk of workplace injury is low. More recently Caplin and Leahy (2001) study the effects on decision-making of anxiety about future payoffs, while Brunnermeier and Parker (2005) study the general problem of optimal beliefs when expectations about the future and memories of the past affect current happiness. If preferences over beliefs about oneself are plausible, then preferences over beliefs about others are surely plausible as well. When giving to Africa, for example, it is hard to see how anything other than beliefs could matter. Second, the model endogenizes beliefs through optimization, in the spirit of Akerlof and Dickens (1982) and Brunnermeier and Parker (2005).

A natural question is whether the resulting beliefs are consistent either internally or with observable data. To examine this I next characterize optimal beliefs. Because the benefactor's

ex post belief  $\hat{\pi}_2$  affects his payoffs only through  $\mathbb{E}_{\hat{\pi}_2}[v(d,\theta)]$ , he will choose to be as optimistic as possible ex post. Specifically, optimal ex post beliefs put full weight on the state

$$\overline{\theta}(d, s_2, s_1) = \arg \max_{\theta \in \Theta: \pi(\theta|s_2, s_1) > 0} [v(d, \theta)]$$
(5)

which is the best state of the world consistent with the information history. Given this, the benefactor's ex ante problem (4) reduces to

$$\max_{\hat{\pi}} \mathbb{E}_{\pi} \left[ u(d^*) + v(d^*, \overline{\theta}) \right]$$
 (6)

suppressing arguments for brevity. In other words, the benefactor holds ex ante beliefs that induce an optimal decision, given that he will ultimately take the optimistic interpretation  $\overline{\theta}$ . As it turns out, these beliefs are Bayesian without loss of generality.

**Lemma 1** (Baysian Updating). There exist optimal subjective beliefs satisfying Bayes' rule.

The proof (Appendix A) is constructive, showing that beliefs derived as conditional probabilities from the prior

$$\hat{\pi}(\theta, s_2, s_1) = 1(\theta = \overline{\theta}(d^*(s_1), s_2, s_1))\pi(s_2, s_1)$$
(7)

are optimal. Intuitively, the benefactor holds an unbiased view  $\pi(s_2, s_1)$  of the *likelihood* of the various kinds of feedback he might receive, but chooses to *interpret* this feedback as proving that a desirable state of the world  $\overline{\theta}$  has been realized. This has several implications.

First, optimal beliefs have the usual mathematical properties of beliefs: for example, they behave as martingales. An empirical researcher therefore cannot identify beliefs as "well intentioned" or not without ancillary data such as the empirical distribution  $\pi$ .

Second, optimal beliefs are consistent with observable data. Formally, the marginal distribution over  $(s_2, s_1)$  implied by (7) is the empirical distribution  $\pi(s_2, s_1)$ , so that the well-intentioned benefactor believes nothing that is not consistent with what he sees. This in turn implies that the beliefs of a benefactor with unbounded time to learn about the model environment through repeated experience could converge to optimal beliefs. Optimal beliefs differ from the objective distribution only in describing data that are unobservable, i.e. the conditional distribution of  $\theta$  given  $(s_2, s_1)$ .<sup>11</sup> In this sense optimization is a relatively mild assumption here compared to models in which agents maintain optimistic interpretations that conflict with observable data.<sup>12</sup>

Third, **optimal beliefs are self-consistent:** a benefactor holding them would not wish to alter them. To see this, note that  $\hat{\pi}$  is a fixed point of (7) (and that this need not hold for the empirical distribution  $\pi$ .) This property does not hold in models such as Brunnermeier

<sup>&</sup>lt;sup>11</sup>The standard argument that agents who have played the same game many times should hold empirical priors thus does not apply here.

<sup>&</sup>lt;sup>12</sup>Brunnermeier and Parker (2005) argue, for example, that "psychological theories provide many channels through which the human mind is able to hold beliefs inconsistent with the rational processing of objective data" (p. 1093), and Mobius et al. (2013) find that lab subjects interpret data about their ability with self-serving biases even when the data generating process is specified unambiguously. The settings envisioned here, such as giving to international charities, provide even greater scope for the imagination.

and Parker (2005) in which agents hold self-inconsistent beliefs, reflecting the tension between between utility from actions and utility from beliefs.

Fourth, the model nests the benchmark case of preferences over outcomes. To see this, consider evidence  $(s_2, s_1)$  that is consistent with only a single state  $\theta : \pi(\theta|s_2, s_1) > 0$ . For such evidence the only admissable interpretation is  $\hat{\pi}(\theta|s_2, s_1) = \pi(\theta|s_2, s_1)$ . Next, call feedback fully revealing if it always uniquely identifies the state, i.e.  $\{\theta \in \Theta : \pi(\theta|s_2, s_1) > 0\}$  is single-valued for any  $(s_2, s_1)$  such that  $\pi(s_2, s_1) > 0$ . One can show that beliefs derived via Bayesian updating from the prior  $\pi(\theta, s_2, s_1)$  are optimal if feedback is fully revealing. The good intentions framework and the standard one thus coincide precisely when the benefactor expects no ex-post ambiguity about  $\theta$ . 14

This last point helps define the model's scope of application. What makes it distinctive is the absence of directly experienced consequences. This is a natural assumption in many situations involving other-regard, since some of the relevant consequences are experienced by other people. In principle, however, the same formalisms could be applied to some purely selfish activities.

# 3 An Example

How informed will a well-intentioned benefactor become? This section illustrates the main ideas in the context of a simple example, using convenient functional forms and taking the decision about how much to give to a specific charity as a leading case. Except where noted, the results here are then generalized to arbitrary functional forms and decisions in Section 4.

#### 3.1 Learning to Give

Don, a marketing executive in Manhattan, considers giving to an NGO working to help Ben, a farmer in Africa. Don can donate any amount d up to total income y. Ben's welfare  $w(d,\theta)$  depends both on this donation and on other exogenous factors such as the level of rainfall or the effectiveness of the NGO. For simplicity, the situation is either Good  $(\theta = \theta^g)$  or Bad  $(\theta = \theta^b)$ , where Ben's preferences satisfy  $v(d,\theta^g) > v(d,\theta^b)$  for all d. Don's prior is that  $\pi(\theta = \theta^g) \equiv \gamma \in (0,1)$ . Don is a pure altruist, maximizing

$$y - d + \hat{\gamma}_2 v(d, \theta^g) + (1 - \hat{\gamma}_2) v(d, \theta^b)$$
 (8)

where  $v(d, \theta) = w(d, \theta)$  and  $\hat{\gamma}_2$  is his subjective ex-post assessment of the likelihood that the situation is good. In each period he either observes  $\theta$  or learns nothing. For example, interpreting  $\theta$  as a measure of NGO effectiveness, he might or might not learn about an impact evaluation of its work. Interpreting  $\theta$  as growing conditions, he might or might not

<sup>&</sup>lt;sup>13</sup>Suppose  $(s_2, s_1)$  is fully revealing; then we can write  $\theta = f(s_2, s_1)$  for some function f. This implies that  $\overline{\theta}(d, s_2, s_1) = f(s_2, s_1)$  and also that  $\pi(\theta, s_2, s_1) = 1(\theta = f(s_2, s_1))\pi(s_2, s_1)$ . We can now apply the construction used to prove Lemma 1 to show that beliefs derived via Bayesian updating from  $\hat{\pi}(\theta, s_2, s_1) = 1(\theta = f(s_2, s_1))\pi(s_2, s_1) = \pi(\theta, s_2, s_1)$  must be optimal.

<sup>&</sup>lt;sup>14</sup>The antecedent can be made both necessary and sufficient by adding appropriate sensitivity conditions.

read news about the state of African agriculture. Let p be the *conditional* probability that he learns it after donating if he had not learned it before.

If Don observes  $\theta$  before donating then this pins down beliefs and he chooses

$$d^*(\theta) \equiv \arg\max_{d} y - d + v(d, \theta) \tag{9}$$

In the more interesting case where he does not learn before donating, he anticipates the views he will hold in the future. With probability p he will learn the true state, while with probability 1-p he will obtain ambiguous information which he will optimally interpret as meaning that all is well  $(\theta = \theta^g)$ . His future perception is thus  $\hat{\gamma}_2 = 0$  with probability  $p(1-\gamma)$  and  $\hat{\gamma}_2 = 1$  with probability  $1-p(1-\gamma)$ . Given this, he optimally interprets the absence of news at time t=1 to mean that matters in Africa are good with probability  $\hat{\gamma}_1 = 1-p(1-\gamma)^{15}$  and gives

$$d^*(\emptyset) \equiv \arg\max_{d} y - d + \hat{\gamma}_1 v(d, \theta^g) + (1 - \hat{\gamma}_1) v(d, \theta^b)$$
 (11)

Don's tendency to take a self-serving view of things shapes his motives for learning. Consider first what happens if he learns the truth ex post, after giving. If he already knew it then of course it has no effect. If it is news to him, however, then it cannot be welcome news. The reason is that, when uninformed, Don optimally reasons that "no news is good news" and believes all is well  $(\theta = \theta^g)$ . Becoming informed thus cannot help and may hurt, forcing him to confront unpleasant realities  $(\theta = \theta^b)$ .

**Observation 1.** Don's expected payoff strictly decreases in the probability that he becomes informed after donating.

This makes explicit the idea that information is primarily a constraint, rather than a resource. Information rules out possibilities that Don might otherwise have been able to believe in. This might seem to suggest that he will never want to learn. This turns out to be true in the limit case where Don is sure to not learn the truth ex post (q = 0). In that case his payoff when also informed ex ante is

$$(\gamma) \left[ \max_{d} y - d + v(d, \theta^g) \right] + (1 - \gamma) \left[ \max_{d} y - d + v(d, \theta^b) \right]$$
(12)

while when he is not informed it is

$$\max_{d} y - d + v(d, \theta^g) \tag{13}$$

He thus obtains a benefit from being uninformed proportional to

$$\max_{d} \left[ y - d + v(d, \theta^g) \right] - \max_{d} \left[ y - d + v(d, \theta^b) \right] \ge \max_{d} \left( v(d, \theta^g) - v(d, \theta^b) \right) > 0 \tag{14}$$

$$\arg\max_{d} y - d + \mathbb{E}_{\hat{\gamma}_{1}}[v(d, \theta)] = \arg\max_{d} y - d + \mathbb{E}_{(1 - p(1 - \gamma))}[v(d, \theta)]$$
(10)

Note that  $\hat{\gamma}_1 = \mathbb{E}_{\pi}[\hat{\gamma}_2]$  so that the evolution of Don's beliefs satisfies the law of iterated expectations and with it Bayes' rule.

 $<sup>^{15}\</sup>mathrm{To}$  see this note that this belief uniquely ensures

The intuition here is the same, that information constrains the imagination. Absent any threat of real consequences, Don prefers maximum scope to "think positive." Yet things are less clearcut when Don faces some real chance of ex post feedback (p > 0). To see this, consider the extreme case p = 1. Don's payoff when informed ex ante is again given by (12), but his payoff when uninformed ex ante is now

$$\max_{d} y - d + (\gamma)v(d, \theta^g) + (1 - \gamma)v(d, \theta^b)$$
(15)

and standard arguments can be used to show that this is less than his informed payoff, so that Don strictly values information. We thus have

**Observation 2.** Don's payoff increases (decreases) in the probability he learns the truth before donating when he will (will not) learn the truth after donating.

Moreover, linearity in p implies that Don's motives for learning before giving are strictly greater the more likely it is that he will eventually learn the truth ex post. His willingness to learn the state ex ante is increasing in the probability that he will learn it ex post, positive only when that probability is sufficiently high, and strictly lower at all interior points than his demand would be if he were making the decision for himself (which is equivalent to p = 1).

This pattern suggests a novel way to think about the value of outcome measurement. Economic analyses often highlight the value of measuring outcomes either in order to tie incentives to them or to enable learning for the future. In the good intentions framework there is an additional effect: measuring outcomes forces altruists to worry about them ex ante, rather than simply act on a plausible hypothesis and hope for the best.

#### 3.2 Nonprofit Marketing

I next examine how Don's attitude towards learning shapes the marketing practices of an intermediary seeking to maximize donations. I focus in particular on the expected returns to generating public information – for example, commissioning a pre-announced randomized controlled trial. This lets me abstract from issues of strategic communication, which introduce a second impediment to learning, and focus exclusively on the role of donor demand.

**Observation 3.** Ex post feedback (higher p) increases (decreases) expected generosity if v is submodular (supermodular).

The probability of ex post feedback affects Don's decision only in the case where he is uninformed ex ante, so that his donation is given by (11). The comparative static is

$$\frac{\partial d}{\partial p} = \frac{(1-\gamma)[v_d(d,\theta^g) - v_d(d,\theta^b)]}{(1-p(1-\gamma))v_{dd}(d,\theta^g) + p(1-\gamma)v_{dd}(d,\theta^b)}$$
(16)

which shares the sign of  $v_d(d, \theta^b) - v_d(d, \theta^g)$ .

**Observation 4.** Suppose that ex ante information does not affect expected generosity when ex post feedback is perfect. Then ex ante information strictly increases (decreases) expected generosity if v is submodular (supermodular) and feedback is limited.

The statement of this result is complicated slightly by the fact that information will generically tend to affect the *expectation* of giving d even in a standard model (p = 1). This is the mechanism for persuasion studied in Kamenica and Gentzkow (2011), for example. To suppress this effect and isolate the *relative* effect of good intentions, define

$$d^*(\gamma) \equiv \arg\max_d y - d + \gamma v(d, \theta^g) + (1 - \gamma)v(d, \theta^b)$$
(17)

Ex ante information thus has no average effect in the p=1 case if  $d^*(\gamma) = \gamma d^*(1) + (1-\gamma)d^*(0)$ . Suppose this holds, and consider the case p<1. If informed ex ante Don's expected donation is again  $\gamma d^*(1) + (1-\gamma)d^*(0)$ . If uninformed his donation solves (11). The solution to this equation is decreasing (increasing) in p if v is supermodular (submodular), and hence Don gives less (more) than  $d^*(\gamma)$  when uninformed.

These two results both share the same underlying mechanism. Because Don prefers to believe that things are going well for Ben, information generally forces him to revise his beliefs negatively. How this affects his donation d then depends on whether giving is more or less impactful when the situation  $\theta$  is bad. If  $\theta$  complements donations – for example, if it measures effectiveness – then forcing Don to confront reality will lower his perception of marginal returns and depress giving. The intermediary has no incentive to do this. If, on the other hand,  $\theta$  substitutes for donations – for example, if it measures Ben's baseline income – then forcing Don to confront reality will raise his perception of marginal returns and increase giving. Put another way, Don wishes to believe Ben is doing well, but the charity needs him to realize that Ben is desperately needy. Both results seem broadly consistent with nonprofit marketing practices, which seem to emphasize "awareness-raising," broad aspirations, and depictions of need heavily relative to concrete information about what will be done with donations and how effective it is.

Notice that the argument here hinges on the specific things Don wishes to believe about the world: that Ben is doing well to begin with, and that his interventions are impactful. As this suggests, I show below that the optimal strategy for a revenue-generating intermediary depends on the motives of the donor. An impact philanthropist, for example, wants to believe both that the need is great and that the intervention is effective; in this case it is optimal for an intermediary to provide no information.

## 3.3 Beneficiary-Optimal Policy

The results above show that revenue-maximizing intermediaries have little incentive to generate evidence on effectiveness. One might expect incentives to be stronger for a policy-maker focused solely on the well-being of the beneficiary (or for the beneficiary himself). Interestingly, in the example above this is not the case. Because Don's only choice is how much to help, Ben is completely aligned with the intermediary in seeking to maximize total donations d. To break this result we need to introduce an additional dimension into Don's choice problem, letting him choose both how much and also how to give. Even then, however, there may exist a tradeoff between the quantity and quality of giving.

To illustrate this, suppose Don can now direct his donation to one of two causes  $c \in \{s, r\}$ ;

s represents a safe cause with certain returns v(d), while r represents a risky one with returns equal to  $\theta v(d)$ . Don's expected payoff is

$$y - d + \begin{cases} (\hat{\gamma}_1 \theta^g + (1 - \hat{\gamma}_1)\theta^b)v(d) & c = r \\ v(d) & c = s \end{cases}$$
 (18)

To make the choice of c non-trivial, assume that  $\theta^g > 1 > \theta^b$ . Don optimally chooses to give to the risky cause if  $\hat{\gamma}_1\theta^g + (1-\hat{\gamma}_1)\theta^b > 1$  and to the safe cause otherwise. This immediately implies that research which reveals the true state (and thus forces Don to believe  $\hat{\gamma}_1 = 1(\theta = \theta^g)$ ) will weakly increase the likelihood that Don gives to the more effective cause. To make this stark, suppose that p = 0, so that Don believes  $\hat{\gamma}_1 = 1$  and gives to the risky cause unless he learns up-front that  $\theta = \theta^b$ . Revealing  $\theta$  in this case strictly increases the probability that Don supports the more effective cause.

Revealing  $\theta$  also affects the total amount he gives, however, which is defined implicitly by the first-order condition

$$v'(d^*(\hat{\gamma}_1)) = \max\{\hat{\gamma}_1 \theta^g + (1 - \hat{\gamma}_1)\theta^b, 1\}$$
(19)

If uninformed, Don gives a total of  $v'^{-1}(\theta^g)$  to the risky cause, while if informed he does the same with probability  $\gamma$  or gives  $v'^{-1}(1)$  to the safe cause with probability  $1 - \gamma$ . The net effect of information on Ben's payoff is thus

$$(1 - \gamma)[v(v'^{-1}(1)) - \theta^b v(v'^{-1}(\theta^g))]$$
(20)

The sign of this expression is ambiguous, as  $\theta^b < 1$  but  $v'^{-1}(\theta^g) > v'^{-1}(1)$ . Intuitively, research that reveals the risky cause to be less effective than Don had hoped leads him to give to a more effective cause, but also leads him to give less overall. On net Ben could be either better or worse-off.<sup>16</sup>

This example highlights a basic tradeoff in the model between the *quantity* and *quality* of altruistic activity; similar results can be obtained for the effect of ex-post feedback. This raises the interesting question whether, for example, it might be better to allow funders to pursue a popular new idea such as micro-lending rather than risk "bursting their bubble" with disappointing evidence. Of course, the model says only that this is possible, not necessarily probable. The quantity/quality tradeoff may also help explain why misguided altruism can persist even in settings where the benefactor and the beneficiary can communicate directly. The beneficiary may find it optimal not to reveal his true needs or preferences if the benefactor is very excited about some other approach. Appendix B illustrates this in a cheap-talk setting.

#### 3.4 Salience and Charitable Giving

Because it emphasizes thoughts rather than outcomes, the framework also helps rationalize some salience-related features of charitable marketing and giving. To see this, consider a simple

<sup>&</sup>lt;sup>16</sup>To verify that the latter is possible, note that we can pick  $\theta^b$  sufficiently close to 1 as to make (20) strictly negative.

extension in which Don thinks about Ben ex post with probability  $\rho$ . His expected payoff is

$$y - d + \rho \left[ \hat{\gamma}_2 v(d, \theta^g) + (1 - \hat{\gamma}_2) v(d, \theta^b) \right]$$
(21)

While the analysis above fixed  $\rho=1$ , endogenizing it has several implications. First, donors give more to causes that are more memorable for them (higher  $\rho$ ). This may help explain why people are more likely to give to issues that have affected friends and loved ones (Small and Simonsohn, 2008). For example, a donor who has lost a loved one to cancer is more likely to remember a gift supporting anti-cancer research through the associate property of memory (e.g. Tulving and Schacter (1990)). As a corollary, charities can increase donations by making them more memorable. The most direct such strategy is of course to frequently remind the donor of his gift, and indeed "thank-you" notes are generally considered a good marketing practice. Less obviously, charities can enhance recall of a gift by associating it with something specific and memorable. Linking a donation to an "identifiable victim" is one such strategy and has been show to increase giving (Jenni and Loewenstein, 1997). The use of "gift catalogues" may play a similar role; these allow donors to visualize their donation as leading to the provision of some specific, tangible thing (e.g. a goat) which they themselves "chose." 18

#### 4 General Results

To articulate more general results I first define comparisons between the information content of signals: a sense in which two signals are the same, and the standard Blackwell sense in which one is more informative than another.

**Definition 1** (Information equivalence). Random variables X and Y are informationally equivalent if there exists a bijection f such that Y = f(X).

**Definition 2** (Blackwell garbling). Let h(x, y, z) give the joint distribution of the random variables (X, Y, Z). X is a Blackwell garbling of Y with respect to Z if h(x|y, z) is independent of z.

The shorthand  $X \succeq Y$  indicates that the benefactor's expected payoff is weakly greater when he observers the random variable X than when he observers Y. We can now generalize Observation 2 and show that the benefactor prefers as little expost feedback as possible.

 $<sup>^{17}\</sup>mathrm{See}$  for example https://www.blackbaud.com/files/resources/downloads/WhitePaper\_RecurringGiving.pdf. Note that in the model Don's taste for reminders is ambiguous because v has no absolute unit: intuitively, thinking about Ben may make Don either happy or sad. Modifying Don's preferences along the lines suggested by Duncan (2004), so that Don cares about the difference his contribution made, resolves this ambiguity in favor of reminders.

<sup>&</sup>lt;sup>18</sup>Gift catalogues are harder to rationalize as mechanisms for control, for two reasons. First, altruistic donors should not want control as they are unlikely to have good information about which interventions are most needed. Second and more importantly, donors' "choices" are typically not legally binding, as the accompanying fine print makes clear that the nonprofit will do whatever it wants with the donation. See for example http://philanthropy.com/article/Holiday-Gift-Catalogs-Are/64374/.

**Proposition 1.** Let random variable  $S'_2$  be a garbling of  $S_2$  with respect to  $(S_1, \theta)$ . Then  $S'_2 \succsim S_2$ .

As above, the intuition is that feedback constrains the benefactor without helping him make decisions.

**Proposition 2.** • Let  $S_1$  be informationally equivalent to  $S_2$ . Then  $S_1 \succsim S_1'$  for any  $S_1'$ .

• Let  $S_1$  be a garbling of  $S_2$  with respect to  $\theta$  and let  $S'_1$  be a garbling of  $S_1$  with respect to  $S_2$ . Then  $S_1 \succeq S'_1$ .

This generalizes Observation 2. The first part states that the benefactor's weakly prefers to observe ex ante what he will eventually observe ex post. In particular, he has no demand for information prior to making his decision that he will not subsequently learn after that decision. The second part states that, among signals that are strictly less informative than what he will observe ex post, the benefactor weakly prefers more informative ones. It is a corollary that he places a (weakly) positive value on such signals, since a white-noise signal is trivially a member of this set.

Generalizing Observation 4 requires a bit more work, as we need a generalization of the idea that ex ante information does not affect expected generosity under standard preferences (or equivalently, when ex post feedback is perfect).

**Definition 3.** Suppose d is real-valued. The benefactor's preferences respect expectation if

$$\arg\max_{d} \mathbb{E}_{\mu}[u(d) + v(d, \theta)] = \mathbb{E}_{\mu}[\arg\max_{d} u(d) + v(d, \theta)]$$
 (22)

holds for any  $\mu \in \Delta(\theta)$ .

This condition says that, while particular realizations of  $\theta$  may influence generosity one way or another, disclosure of  $\theta$  neither increases nor increases generosity in expectation. We can now state and prove a general result on complementary and substitutability:

**Proposition 3.** Suppose that  $\Theta$  is ordered, D is real-valued, and  $v(d,\theta)$  is increasing in both arguments.

- Let  $S'_2$  be a garbling of  $S_2$  with respect to  $\theta$ . Then  $\mathbb{E}_{\pi}[d]$  is higher (lower) under  $S'_2$  than under  $S_2$  if v is supermodular (submodular).
- Let  $S'_1$  be a garbling of  $S_1$  with respect to  $(S_2, \theta)$  and suppose that the benefactors preferences respect expectation. Then  $\mathbb{E}_{\pi}[d]$  is higher (lower) under  $S'_1$  than under  $S_1$  if v is supermodular (submodular).

In the case of pure altruism (v = w) the properties of v which determine Proposition 3 are simply inherited from w. Thus, for the case of pure altruism the result implies that generosity tends to increase when information about needs is disclosed, but tends to decrease when information about effectiveness is disclosed. It also establishes the generality of the tradeoff between the quality and quantity of generosity discussed in Section 3.3

When the benefactors holds motives other than pure altruism, on the other hand, the wedge between benefactor (v) and beneficiary (w) preferences can generate different incentives for

intermediaries. Preferences of the reference-dependent form in Equation (2) are an interesting and tractable case, nesting motives ranging from impact  $(\bar{d} = \min D)$  to guilt (which one can isolate by considering  $\bar{d} = \max D$ ). One can then show

**Proposition 4.** Suppose that the benefactor's preferences are as in (2),  $\Theta$  is ordered, D is real-valued,  $w(d, \theta)$  is increasing in both arguments, and  $w_d(d, \theta)$  is monotonic in  $\theta$ .

- Let  $S'_2$  be a garbling of  $S_2$  with respect to  $\theta$ . Then  $\mathbb{E}_{\pi}[d]$  is higher (lower) under  $S'_2$  than under  $S_2$  if  $\overline{d} = \min D$  ( $\overline{d} = \max D$ ).
- Let  $S'_1$  be a garbling of  $S_1$  with respect to  $(S_2, \theta)$  and suppose that the benefactors preferences respect expectation. Then  $\mathbb{E}_{\pi}[d]$  is higher (lower) under  $S'_1$  than under  $S_1$  if  $\overline{d} = \min D$  ( $\overline{d} = \max D$ ).

This result says that donor motivations matter for market intermediaries. For a revenue-maximizing intermediary facing an impact philanthropist, the optimal strategy is to provide no information at all, including (ironically) information about impact. The intuition is that impact philanthropists want to believe in exactly those things that make the marginal return on their giving (and hence, the level of their giving) high. For example, a charitable donor motivated by impact wants to believe that the charity he supports is extremely effective and serves a disparately needy population. The intermediary is best-off facilitating this wishful thinking by providing no information, leaving the donor free to hold the beliefs most conducive to giving.<sup>19</sup>

The reverse is true for guilty givers. These donors want to believe ex-post that even taking the most generous possible action  $\overline{d}$  would have made little difference, so that they need not feel guilt. Such donors may seek to convince themselves, for example, that the need is not very great, or that all foreign aid is corrupt and never actually reaches people in need. This lets them give very little without experiencing guilt over missed opportunities. A fundraiser pitching such a donor thus benefits in expectation from the release of evidence of both need and efficacy. The donor would of course want to avoid this pitch.

# 5 Conclusion

Standard models of other-regarding behavior model benefactors with preferences over a beneficiary's outcomes. This approach is unrealistic, as it posits that the decision-maker has preferences over events he never experiences. I study an alternative framework in which the benefactor has preferences over his beliefs about the beneficiary's outcomes. This framework nests the standard model in the special case where the benefactor obtains complete ex post information about the beneficiary's outcomes; absent perfect feedback the models' predictions diverge. Consistent with the motivation for the framework, the benefactor in the model endogenously prefers to avoid ex post feedback and also avoids ex ante information about the

<sup>&</sup>lt;sup>19</sup>The impact philanthropy case may also help explain the success of fundraising based on "matching grants." These would seem to face a credibility challenge: if a large donor offers to match smaller donations, it seems likely that he might give even if those smaller donations do not materialize. An impact donor, however, has a strong incentive to believe that the commitment is in fact credible, since this increases his marginal impact. Fortunately for him, there is unlikely to be unambiguous evidence to the contrary.

beneficiary except to avoid subsequent disappointment. The results may help explain a range of puzzles about effective giving ranging from poorly chosen holiday gifts to misspent charitable donations and foreign aid.

While static, the framework developed here is dynamically consistent in the sense that the benefactor holds beliefs that match the true distribution of observable variables. Formally modelling a dynamic extension could potentially shed further light on the evolution of altruism. Two specific conjectures seem worth examining. First, benefactor behavior will be self-perpetuating. A benefactor who takes an arbitrary action at time t will be motivated to believe this action was effective at time t+1, which will in turn motivate him to repeat the action. This may explain why nonprofits place such priority on the initial acquisition of donors. Second, benefactors may tend to become "jaded" over time as the accumulation of evidence increasingly constrains the extent to which they can "think positive."

# A Proofs

#### Proof of Lemma 1

Beliefs consistent with Bayes' rule must satisfy

$$\hat{\pi}(\theta, s_2 | s_1) \hat{\pi}(s_1) = \hat{\pi}(\theta, s_2, s_1)$$
$$\hat{\pi}(\theta | d, s_2, s_1) \hat{\pi}(s_2, s_1) = \hat{\pi}(\theta, s_2, s_1)$$

for all  $(\theta, s_2, s_1)$ . Consider the following family of history-contingent subjective beliefs:

$$\hat{\pi}(\theta, s_2, s_1) = 1(\theta = \overline{\theta}(d^*(s_1), s_2, s_1))\pi(s_2, s_1)$$
(23)

$$\hat{\pi}(\theta, s_2|s_1) = 1(\theta = \overline{\theta}(d^*(s_1), s_2, s_1))\pi(s_2|s_1)$$
(24)

$$\hat{\pi}(\theta|d, s_2, s_1) = 1(\theta = \overline{\theta}(d, s_2, s_1)) \tag{25}$$

where

$$d^*(s_1) = \arg\max_{d} \mathbb{E}_{\pi(s_2|s_1)}[u(d) + \mathbb{E}_{\hat{\pi}(\theta|d,s_2,s_1)}[v(d,\theta)]]$$
 (26)

is the action the benefactor takes given these beliefs. It is straightforward to verify that the beliefs thus defined satisfy Bayes rule following any signal realizations. Intuitively, the benefactor retains objective beliefs about the distribution of signals  $(s_2, s_1)$  but distorts their interpretation, i.e. what these signals reveal about  $\theta$ . To show that these beliefs also maximize the benefactor's payoff we need to show that they satisfy two conditions. First, if  $\Theta(s_2, s_1)$  denotes the set of admissible beliefs upon observation of  $(s_2, s_1)$  then  $\hat{\pi}(\theta|d, s_2, s_1)$  must solve

$$\max_{\tilde{\pi} \in \Theta(s_2, s_1)} \mathbb{E}_{\tilde{\pi}}[v(d, \theta)] \tag{27}$$

which it evidently does by definition. Second,  $\hat{\pi}(\theta, s_2|s_1)$  is optimal if (though not necessarily only if) it induces the action that is optimal, i.e.

$$\arg\max_{d} \left[ u(d) + \mathbb{E}_{\hat{\pi}(s_2|s_1)}[v(d,\theta)] \right] = \arg\max_{d} \left[ u(d) + \mathbb{E}_{\pi(\theta,s_2|s_1)} \mathbb{E}_{\hat{\pi}(\theta|d,s_2,s_1)}[v(d,\theta)] \right]$$
(28)

This condition holds if

$$\hat{\pi}(\theta|s_1) = \mathbb{E}_{\pi(s_2|s_1)}[\hat{\pi}(\theta|d, s_2, s_1)] \tag{29}$$

$$= \mathbb{E}_{\pi(s_2|s_1)}[1(\theta = \overline{\theta}(d, s_2, s_1))]$$
 (30)

$$= \sum_{s_2} 1(\theta = \overline{\theta}(d, s_2, s_1)) \pi(s_2 | s_1)$$
(31)

which follows from the definition of  $\hat{\pi}(\theta, s_2|s_1)$  above.

## **Proof of Proposition 1**

Fix a realization  $s_1$ . The benefactor's expected payoff if he observes  $S_2$  is

$$u(d^*) + \sum_{s_2} \left[ \max_{\theta \in \Theta(s_2, s_1)} \{ v(d^*, \theta) \} \right] \pi(s_2 | s_1)$$
 (32)

where  $d^*$  is a decision that maximizes this expression. Now suppose instead he observes the realization of  $S'_2$ . Since  $d^*$  remains a feasible decision his payoff cannot be less than

$$u(d^*) + \sum_{s_2} \sum_{s_2'} \left[ \max_{\theta \in \Theta(s_2', s_1)} v(d^*, \theta) \right] \pi(s_2'|s_2, s_1) \pi(s_2|s_1)$$
(33)

Now consider some realization  $(s'_2, s_2, s_1, \theta)$  observed with positive probability such that  $\pi(s_2, s_1, \theta) > 0$  so that  $\theta \in \Theta(s_2, s_1)$ . We can write

$$\pi(s_2', s_2, s_1, \theta) = \pi(s_2'|s_2, s_1, \theta)\pi(s_2, s_1, \theta)$$
$$= \pi(s_2'|s_2)\pi(s_2, s_1, \theta)$$
$$> 0$$

where the second step follows from the fact that  $S'_2$  garbles  $S_2$  with respect to  $(S_1, \theta)$  and the third from the fact that  $s'_2$  is observed. Thus for any realization we have  $\Theta(s_2, s_1) \subseteq \Theta(s'_2, s_1)$ . This implies that the maximum in (33) is at least as great as that in (32) for any particular  $(s'_2, s_2)$  and hence (33) is also greater in expectation. Since (33) is a lower bound on the benefactor's payoff when observing  $S_2$ , his actual payoff must also be weakly greater.

#### Proof of Proposition 2

*Proof.* Part 1. Fix the distribution of  $S_2$ . First note that because the benefactor chooses d after observing  $s_1$  but then chooses  $\overline{\theta}$  after observing both  $s_2$  and  $s_1$ , his payoff is bounded above by

$$U(s_2, s_1) \equiv \max_{d, \theta \in \Theta(s_2, s_1)} u(d) + v(d, \theta)$$
(34)

which is the payoff he would obtain if he could choose d after observing both signals. Next, observe that when  $S_1$  is equivalent to  $S_2$  then the benefactor achieves this upper bound. Finally, note that when  $S_1$  is not equivalent to  $S_2$  then

$$\Theta(s_2, s_1) = \{ \theta \in \Theta : \pi(\theta | s_2, s_1) > 0 \}$$
(35)

$$\subseteq \{\theta \in \Theta : \pi(\theta|s_2) > 0\} \tag{36}$$

$$=\Theta(s_2) \tag{37}$$

and hence the constraint in (34) is weakly tighter than when  $S_1$  is equivalent to  $S_2$ , so that  $U(s_2, s_1)$  is weakly lower. Since this is an upper bound on the benefactor's payoff it implies that his realized payoff must also be weakly lower than when  $S_1$  is equivalent to  $S_2$ .

Part 2. The proof follows the standard argument showing that information weakly im-

proves decision-making, with the caveat that we must also establish that observing a garbling of  $S_2$  does not impose any additional constraints on beliefs.

Fix a realization  $s_1$  of  $S_1$ . The benefactor's payoff when he observes this is

$$u(d^*) + \sum_{s_2} v(d^*, \overline{\theta}(d^*, s_2, s_1) \pi(s_2 | s_1)$$
(38)

where  $d^*$  is the decision that maximizes this expression. If instead the benefactor were to observe  $s'_1$  then his payoff, again conditional on the (unobserved) value of  $s_1$ , is

$$u(d(s_1')) + \sum_{s_2} v(d(s_1'), \overline{\theta}(d(s_1'), s_2, s_1') \pi(s_2 | s_1', s_1)$$
(39)

where  $d(s'_1)$  is the optimal decision given  $s'_1$ . To simplify this expression note that

$$\pi(s_2|s_1', s_1) = \frac{\pi(s_1'|s_2, s_1)\pi(s_2|s_1)\pi(s_1)}{\pi(s_1', s_1)}$$
$$= \frac{\pi(s_1'|s_1)\pi(s_2|s_1)\pi(s_1)}{\pi(s_1', s_1)}$$
$$= \pi(s_2|s_1)$$

where the key second step follows since  $s'_1$  is a garbling of  $s_1$  with respect to  $s_2$ . Note also that

$$\Theta(s_2, s_1) = \{\theta : \pi(\theta, s_2, s_1) > 0\}$$

$$= \{\theta : \pi(s_1 | s_2, \theta) \pi(s_2, \theta) > 0\}$$

$$= \{\theta : \pi(s_1 | s_2) \pi(s_2, \theta) > 0\}$$

$$= \{\theta : \pi(s_2, \theta) > 0\}$$

where the third step follows since  $s_1$  is a garbling of  $s_2$  with respect to  $\theta$  and the last since  $\pi(s_1|s_2) > 0$  for any observed realization. This implies that  $\overline{\theta}(d, s_2, s_1)$  does not depend on  $s_1$ . An analogous argument shows that  $\overline{\theta}(d, s_2, s_1')$  does not depend on  $s_1'$ . Exploiting these two facts we can rewrite (39) as

$$u(d(s_1')) + \sum_{s_2} v(d(s_1'), \overline{\theta}(d(s_1'), s_2, s_1)\pi(s_2|s_1)$$
(40)

which must by definition be weakly less than (38) since  $d^*$  is defined as the decision that maximizes that expression.

# **Proof of Proposition 3**

*Proof.* Part 1. Conditional on  $s_1$ , we can write the benefactors objective function as

$$f(d, \{x(s_2', s_2, s_1)\}) \equiv u(d) + \sum_{s_2} \sum_{s_2'} v(d, x(s_2', s_2, s_1)) \pi(s_2'|s_2) \pi(s_2|s_1)$$
(41)

where

$$x(s_2', s_2, s_1) = \max\{\theta : \pi(\theta, s_2, s_1) > 0\}$$
(42)

in the case where he observes  $S_2$  and

$$x(s_2', s_2, s_1) = \max\{\theta : \pi(\theta, s_2', s_1) > 0\}$$
(43)

in the case where he observes  $S'_2$ . (Note that we can write the distribution of  $S'_2$  in this separable form because it garbles  $S_2$  and that x does not depend on d since v is monotone in  $\theta$ .) Examining f, its latter argument is an element of a lattice with dimension support  $(S_2) \times \text{support}(S'_2)$ ; moreover since  $S'_2$  garbles  $S_2$  we have  $\max\{\theta: \pi(\theta, s'_2, s_1) > 0\} \geq \max\{\theta: \pi(\theta, s_2, s_1) > 0\}$  for any realization  $(s'_2, s_2)$ , so that  $S'_2$  induces a weakly larger element of this lattice than  $S_2$ . It then follows from the monotone comparative statics theorem (Milgrom and Shannon, 1994) that the solution is weakly greater (smaller) under  $S'_2$  if v is supermodular (submodular).

**Part 2.** Conditioning on any realization  $s'_1$  of  $S'_1$ , the expected effect of observing  $S_1$  instead can be written as

$$\sum_{s_1} \left[ \arg \max_{d} u(d) + \sum_{s_2} v(d, \overline{\theta}(s_2, s_1)) \pi(s_2 | s_1) \right] \pi(s_1 | s_1')$$

$$- \arg \max_{d} u(d) + \sum_{s_2} v(d, \overline{\theta}(s_2, s_1')) \pi(s_2 | s_1')$$

$$(44)$$

Note that this statement exploits the fact that  $S_1$  is finer than  $S_1'$  to write  $\pi(s_2|s_1,s_1') = \pi(s_2|s_1)$  and  $\overline{\theta}(s_2,s_1,s_1') = \overline{\theta}(s_2,s_1)$ . By adding and substracting we can decompose this difference further as follows:

$$\sum_{s_{1}} \left[ \arg \max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s_{1})) \pi(s_{2}|s_{1}) \right] \pi(s_{1}|s'_{1}) - \sum_{s_{1}} \left[ \arg \max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s'_{1})) \pi(s_{2}|s_{1}) \right] \pi(s_{1}|s'_{1}) - \left[ \arg \max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s'_{1})) \pi(s_{2}|s_{1}) \right] \pi(s_{1}|s'_{1}) - \arg \max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s'_{1})) \pi(s_{2}|s'_{1})$$
(45)

This decomposition highlights two distinct effects of information. The first is the constraint effect: observing  $S_1$  rather than  $S'_1$  places additional restrictions on what the benefactor can reasonably believe ex post. The second is a prediction effect: observing  $S_1$  gives the benefactor a more precise prediction of  $S_2$ . The proof proceeds by showing that (a) the constraint effect has the sign predicted by the theorem, and (b) the prediction effect is zero when the benefactor's preferences respect expectation.

(a) It is enough to show the result for any particular realization  $(s_1, s'_1)$ . Consider therefore

$$\arg\max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s_{1})) \pi(s_{2}|s_{1}) - \arg\max_{d} u(d) + \sum_{s_{2}} v(d, \overline{\theta}(s_{2}, s'_{1})) \pi(s_{2}|s_{1})$$
(46)

By the same argument used above to prove part 1 of the proposition this difference is negative (positive) if v is supermodular (submodular). Intuitively, information tends to force the donor to hold a less optimistic view of  $\theta$ , which increases generosity if and only if d and  $\theta$  are substitutes.

#### (b) The prediction effect can be written as

$$\mathbb{E}\left[\arg\max_{d} u(d) + \mathbb{E}[v(d,\overline{\theta})|S_1]\right] - \arg\max_{d} u(d) + \mathbb{E}\left[v(d,\overline{\theta})\right]$$
(47)

for appropriate priors (which I suppress for brevity). Since preferences respect expectation we know that

$$\mathbb{E}\left[\arg\max_{d} u(d) + v(d, \overline{\theta})\right] = \arg\max_{d} u(d) + \mathbb{E}\left[v(d, \overline{\theta})\right]$$
(48)

Moreover since this property holds for any prior we can apply it a second time after conditioning on a realization  $s_1$  to show that

$$\mathbb{E}\left[\arg\max_{d} u(d) + v(d, \overline{\theta})|s_1\right] = \arg\max_{d} u(d) + \mathbb{E}[v(d, \overline{\theta})|s_1]$$
(49)

Taking expectations of both sides over  $S_1$  yields

$$\mathbb{E}\left[\arg\max_{d} u(d) + v(d, \overline{\theta})\right] = \mathbb{E}\left[\arg\max_{d} u(d) + \mathbb{E}[v(d, \overline{\theta})|S_{1}]\right]$$
(50)

which together with (48) implies that (47) is zero.

#### **Proof of Proposition 4**

*Proof.* Part 1. Given d and the realization  $(s_2, s_1)$  the benefactor's ex-post problem is

$$\max_{\theta \in \Theta(s_2, s_1)} w(d, \theta) - w(\overline{d}, \theta) \tag{51}$$

Since  $w_d(d,\theta)$  is monotone in  $\theta$ , the solution to this problem must also solve  $\max_{\theta \in \Theta(s_2,s_1)} w_d(d,\theta)$  for any d if  $d \geq \overline{d} = \min D$ , and  $\min_{\theta \in \Theta(s_2,s_1)} w_d(d,\theta)$  for any d if  $d \leq \overline{d} = \max D$ . It follows that further constraining the benefactor's ex-post beliefs by revealing additional information will decrease (increase) the expected value of  $v_d(d,\theta)$  for any d, and thus weakly decrease (increase) his expected donation, when  $\overline{d} = \min D$  ( $\overline{d} = \max D$ ).

Part 2. The argument proceeds exactly as in the proof of Part 2 of Proposition 3. The effect of coarser information has two effects, a constraint effect and a prediction effect; the prediction effect is zero when preferences respect expectation, while the sign of the constraint effect depends on  $\bar{d}$  as in Part 1 above.

# **B** Communication

A core result in the model is that benefactors may not want information about the impact of their actions, since new information may limit the extent to which they can believe in good outcomes. In some settings this result is decisive, but in others the beneficiary may also have opportunities to communicate information to the benefactor. For example, givers and receivers of holiday gifts may talk beforehand about the kinds of things the receiver likes. It is therefore worth understanding whether such communication will tend to eliminate information asymmetries between the two. A full analysis of this issue is beyond the scope of the paper, but I provide her an example to illustrate that the beneficiary may find it in her best interest to conceal information from the benefactor.

## B.1 An Example, Continued

Don, the Manhattan marketing executive, is again contemplating a donation to help Ben, the African farmer. Don has become aware of two different NGOs both of which work in Ben's village but which provide different services, and must decide how much to donate to each. Let  $d = (d^a, d^b)$  represent his giving, where  $d^a, d^b \ge 0$  and Don's budget constraint is  $d^a + d^b \le y$ . Ben's preferences are represented by

$$v(d,\theta) = \theta^a d^a + \theta^b d^b \tag{52}$$

The interpretation is that  $\theta^i$  measures the marginal impact of intervention i on Ben's welfare. Don is uncertain about these impacts, knowing only that they are drawn from distribution  $\pi$  with support on  $[\underline{\theta}^a, \overline{\theta}^a] \times [\underline{\theta}^b, \overline{\theta}^b]$  where  $\underline{\theta}^a > 0$ ,  $\underline{\theta}^b > 0$ . Don does want to help in the way he perceives to be most effective; he seeks to maximize

$$u(y - d^a - d^b) + \mathbb{E}_{\hat{\pi}}[\theta^a d^a + \theta^b d^b] \tag{53}$$

Don does not anticipate any feedback on the impact his donations have. Before he gives, however, Ben has an opportunity to send him a costless message m from some arbitrary set M.

Because he does not anticipate any feedback, Don finds it optimal to hold the same beliefs about the effectiveness of each intervention both before and after donating. In particular if he chooses to fund intervention i then he will optimally interpret Ben's message m to mean that

$$\hat{\pi}(\theta^i = x|m) = 1(x = \max\{\theta^i : \mathbb{P}(m|\theta^i) > 0\})$$
(54)

In other words, Don holds the most optimistic view of the intervention he is funding that is also consistent with Ben's message. Denoting by

$$\overline{\theta}^{i}(m) = \max\{\theta^{i} : \mathbb{P}(m|\theta^{i}) > 0\}$$
(55)

the most optimistic view of intervention i given message m, Don thus donates to intervention

$$i^*(m) = \arg\max_{i \in \{a,b\}} \{\overline{\theta}^i(m)\}$$
 (56)

and gives a total donation  $d^*(m)$  characterized by

$$u'(y - d^*(m)) = \overline{\theta}^{i^*(m)}(m) \tag{57}$$

Given this, Ben's problem is to choose a message m solving

$$\max_{m \in M} d^*(m)\theta^{i^*(m)} \tag{58}$$

This expression highlights the fact that Ben's communication decisions must trade off two goals: he wants to steer Don towards the more effective intervention, but also wants to encourage Don to give generously to whichever intervention he chooses.<sup>20</sup> His credibility on these topics, however, is very different. Don knows that Ben has no direct incentive to lie about *which* kind of help he prefers. He does have a direct incentive to mislead Don about the effectiveness of this intervention, since he would always prefer that Don give more, while Don trades off this help against his private benefits of consumption.

Formally, it follows immediately from inspection of (58) that any equilibrium must be action-equivalent to an equilibrium in which Ben chooses at most one message that induces Don to donate to each intervention. The reason is simply that if two messages m, m' both induced intervention a (say) and  $d^*(m) < d^*(m')$  then Ben would always prefer to send message m'. Hence we can without loss of generality restrict attention to equilibria in which Ben sends at most two messages with positive probability,  $m^a$  inducing a or  $m^b$  inducing b. This in turn lets us characterize a unique recipient-optimal equilibrium. To do so define  $\overline{\theta}^i = \max\{\theta^i\}$  as the most optimistic view about intervention i given priors  $\pi$ . Then we have

**Observation 5.** There exists a unique equilibrium in which Don gives  $d^*(\overline{\theta}^a)$  to a if  $\theta^a d^*(\overline{\theta}^a) \geq \theta^b d^*(\overline{\theta}^b)$  and gives  $d^*(\overline{\theta}^b)$  to b otherwise.

*Proof.* By the argument above, in any equilibrium strategy Don either gives  $d^*(m^a)$  to a or  $d^*(m^b)$  to b. Ben's problem thus amounts to choosing between the payoffs  $\theta^a d^*(m^a)$  and  $\theta^b d^*(m^b)$ . It follows that in any equilibrium Ben sends message  $m^a$  if and only if

$$\frac{\theta^a}{\theta^b} \ge \frac{d^*(m^b)}{d^*(m^a)} \tag{59}$$

Given this, Don's optimal donation level  $d^a$  on observing  $m^a$  must satisfy

$$u'(y - d^*(m^a)) = \max \left\{ \theta^a : \exists \theta^b \text{ such that } \pi(\theta^a, \theta^b) > 0 \text{ and } \frac{\theta^a}{\theta^b} \ge \frac{d^*(m^b)}{d^*(m^a)} \right\}$$

$$= \overline{\theta}^a$$
(61)

<sup>&</sup>lt;sup>20</sup>Provided  $\theta^i \geq 0$ . Consider this case for now.

where the second step follows from the assumption that  $\pi$  has full support on an interval in  $\mathbb{R}^2$ . Similarly, Don's donation on observing  $m^b$  is given by  $u'(y-d^*(m^b))=\overline{\theta}^b$ . This uniquely determines  $\frac{d^*(m^b)}{d^*(m^a)}$ . If this quantity lies within  $\left[\frac{\theta^a}{\overline{\theta}^b}, \overline{\frac{\theta}{\theta}^a}\right]$  then it defines a unique interior equilibrium; in this case there is some communication in equilibrium. If on the other hand it is greater than  $\overline{\frac{\theta}{\theta}^b}$  then Ben only sends  $m^b$ , while if it is less than  $\frac{\theta^a}{\overline{\theta}^b}$  then Ben only sends  $m^a$ ; in these cases nothing is communicated in equilibrium.

This equilibrium generically features a distortion away from the most effective intervention. To see this, consider the most interesting case in which there is non-trivial communication in equilibrium. In order to maximize effectiveness Ben would like to recommend intervention a if and only if  $\theta^a \geq \theta^b$ . In equilibrium, however, he gets intervention a when  $\theta^a d(\overline{\theta}^a) > \theta^b d(\overline{\theta}^b)$ . These conditions coincide only if  $\theta^a = \theta^b$ ; otherwise they diverge, and Ben is either too likely to get one or the other intervention.

The basic issue here is intuitive. For any given amount Don spends, he and Ben would both prefer that he spend it on the most effective intervention. This motivates Ben to inform Don if the intervention he is considering is not in fact the best. Ben also realizes, however, that if Don is excited about the potential of one intervention then disillusioning him may not only affect how he helps but also how much. He may therefore optimally allow Don to retain a mistakenly optimistic view of some "pet" intervention, preferring a lot of somewhat useful help to a smaller amount of more impactful giving.<sup>21</sup>

The result indicates that the size of this distortion depends on the relative magnitude of  $\overline{\theta}^a$  and  $\overline{\theta}^b$ . If the two interventions allow similar scope for optimism or have similar "upside potential" then distortions will be minimized. For example, there should be little bias in conversations about the best way to achieve some fixed goal. If not then there will be a bias towards the intervention with more upside potential at the expense of the one with the higher expected return; in extreme cases where  $\underline{\theta}^a d(\overline{\theta}^a) > \overline{\theta}^b d(\overline{\theta}^b)$  communication breaks down entirely. Note that because bias is driven by upside this implies that donors will tend to be biased towards relatively new, untested interventions whose potential upside is still very high at the expense of older, more tested interventions whose effects are well-known – a bias which gives rise in a natural way to "fads."

<sup>&</sup>lt;sup>21</sup>While the details differ, the basic tension here parallels that in Che et al. (2013). They study a model in which an agent advises a decision-maker on which of several discrete projects to implement. Given perfect information the decision-maker and agent have identical preferences over these projects, but the decision-maker also places positive value on an "outside option" which is worthless to the agent. This tension introduces distortions in communication, with the better-informed agent sometimes recommending inferior projects in order to prevent the decision-maker from exercising his outside option.
